or vestigial plastids as is often erroneously reported (Figure 4). Examination of published electron micrographs (Klintworth et al. 1968; Patni and Aaronson 1974; Joshi et al. 1975; Kaplan 1978; Cheville et al. 1984; Font and Hook 1984; Jensen et al. 1998) supports the claim that no leukoplasts or thallocoid structures are present. The sporangium is spheroidal or an enlarged version of the sporangiospore. The sporangiospores are usually spheroidal or ellipsoidal, but reniform and falcate strains occur. The fact that a Dauer cell stage resists staining with methylene blue and rose Bengal is of significance in identification (Pore 1998). Sexual stages are not found (Pore 1985). Three other species – *P. moriformis*, *Prototheca stagnora*, and *Prototheca ulmea* – which have been isolated from nature, but not from animal infections, all have a large capsule that may give a resemblance to *Cryptococcus* spp. (de Camargo and Fischman 1979; Pore 1985, 1986).

PHYSIOLOGY

Chlorophyll is not present in the *Prototheca* spp. Glucose is assimilated oxidatively and the assimilation of a few other carbon substrates has taxonomic significance (Pore 1985). D-Lactic acid is produced from glucose by

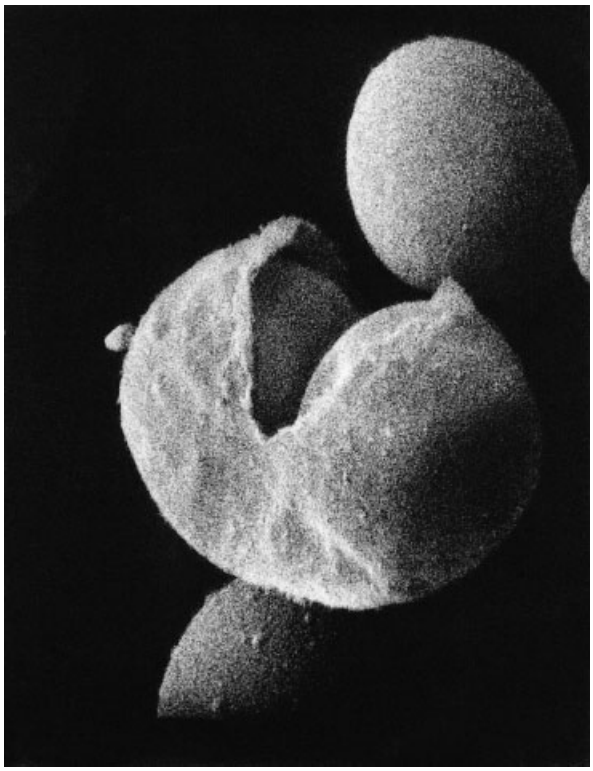

Figure 3 P. wickerhamii *releasing sporangiospores from the sporangium. Scanning electron micrograph; magnification* × *9 350. (Courtesy of Phillip Allender)*

P. zopfii (Barker 1935; Ueno et al. 2002) and other species also produce acid, but not gas, from glucose (unpublished results). Ueno et al. (2002) do report CO_2 production during fermentation as a function of temperature. Ammonium chloride can be assimilated as a sole nitrogen source, but nitrate can not (Pore 1972). Frequently, authors erroneously report starch to be present, but glycogen is the storage carbohydrate (Manners et al. 1973) and starch is absent (Pringsheim 1963). Thiamine (Anderson 1945) and oxygen (Barker 1935) are required for growth. *Prototheca* spp. may store lipids up to 10 percent by weight (Atkinson et al. 1972; Sud and Feingold 1979). The fatty acids 16:0, 18:1, and 18:2 (palmitic, oleic, and linoleic acids) were the predominant extractable lipids of *P. zopfii* grown on glucose or hexadecane (Boehm 1984). Growth on fatty acids (Barker 1935) may well be a reason for the ubiquity of *Prototheca* spp. in fatty acid-enriched wastewater (Pore and Boehm 1986). Assimilation of hexadecane and other hydrocarbons is a notable feature of some strains of *P. zopfii* (Walker and Pore 1978; Pore 1983; Boehm 1984). The cycloartnol-ergosterol biosynthetic pathway of *P. wickerhamii* differs from the lanosterol-ergosterol pathway of yeasts, yet azoles remain effective inhibitors of growth (Mangla and Nes 2000). Ergosterol was not detected in *Prototheca* spp. (unpublished results).

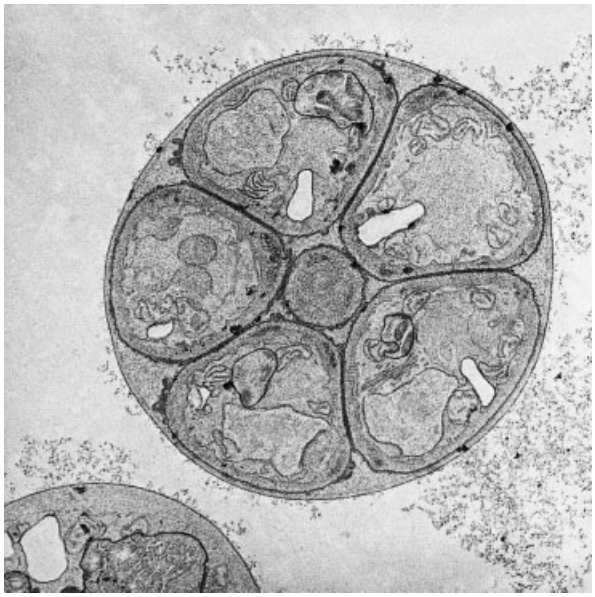

Figure 4 P. wickerhamii *sporangium thin section demonstrating five sporangiospores. Nuclei, mitochondria, Golgi and glycogen storage organelles are present. Transmission electron micrograph; magnification* × *16 250*

The outermost trilaminar aspects of the cell walls of *Prototheca* spp. resist acid and alkaline hydrolysis and contain neither cellulose (as sometimes erroneously reported) nor chitin (Conte and Pore 1973). Atkinson et al. (1972) proposed that sporopollenin could be the refractory compound in the cell walls responsible for resistance to hydrolysis, but the current status of this proposal is that sporopollenin is not the compound in the outermost nonhydrolysable trilaminar cell wall layers (Puel et al. 1987). Regardless of the resolution of this question, the unique cell wall of *Prototheca* spp. and its role in pathogenesis and ecology is a relevant topic for speculation. The presence or absence of carotenoids, accessory photosynthesis pigments, and the purported monomers of sporopollenin would all help in the resolution of the question. Another potentially significant component of the cell envelope of *P. zopfii* is an immunoreactive linear β(1,6)-galactopyranosyl (Manners et al. 1973; Roy et al. 1981). Significant quantities of similar galactans can be easily extracted and purified from the capsules of *P. zopfii* and *P. moriformis* grown in bioreactors. These viscous, polyanionic galactans contain variable amounts of arabinose and rhamnose (unpublished results) and could have medical or industrial value. Likewise, *P. zopfii* and *P. moriformis* have been shown to produce commercial quantities of L-ascorbic acid (Running et al. 2002).

Identification

Five species of *Prototheca* are currently valid, but only two are documented pathogens. Table 2 provides the minimum information needed to differentiate *P. wickerhamii* from *P. zopfii*. For a complete means to

Table 2 *Abbreviated key to differentiate the pathogenic species of* Prototheca[a]

Species	Sporangiospore diameter on PIM[b] (μm) [usual results]	Trehalose assimilation on PIM[c] [no exceptions]
P. wickerhamii	<4.3	+
P. zopfii	>5.7	–

b) *Prototheca* isolation medium.
c) Modified for assimilation testing (Pore 1985, 1998).

differentiate all five species the reader is referred to Pore (1985, 1986, 1998).

PROTOTHECA WICKERHAMII

P. wickerhamii grows on PIM after 3–5 days as a white yeast-like colony. In many respects the colony resembles *Candida* spp. (Figure 5a). The small, usually smooth colonies (Figure 5b) characteristically develop a tan pigmentation with advanced age (2–10 weeks) on Sabouraud's medium. All cell stages are spheroidal in culture. Sporangiospores are 2.5–4.5 μm (mean 3.2), sporangia are 7–13 μm (mean 9.4), and Dauer cells are 5.5–8.5 μm (mean 6.5) in diameter. Temperature optima are usually above 25°C and pathogenic strains grow at 37°C. It is the only species that assimilates trehalose (Arnold and Ahearn 1972). The API 20C carbohydrate assimilation (Padhye et al. 1979) and the API ZYM tests (Casal et al. 1985) are of value for clinical identification. A monograph containing a complete taxonomic description was prepared by Pore (1985).

PROTOTHECA ZOPFII

After growing for 3–5 days on PIM, the colonies are whitish with a wrinkled, yeast-like appearance (Figure 5b). The colonies are faster growing and larger than those of *P. wickerhamii* and the sporangia, ranging up to 25 μm in diameter, give a 'ground-glass' appearance when colonies are observed with a stereomicroscope (magnification × 25). Cells are commonly spheroidal or ellipsoidal, waxy, and hydrophobic. Newly released sporangiospores are spheroidal (4.5–7.5, mean 6.5 μm) or ellipsoidal (3–7 × 5–8, mean 5.5 × 6.5 μm). Dauer cells are spheroidal (8.5–14, mean 11 μm) or ellipsoidal (6–11 × 8.5–13, mean 9.5 × 11.5 μm), and sporangia are spheroidal (14–25, mean 17.3 μm) or ellipsoidal (11–20 × 14–23, mean 14.5 × 16.5 μm), but morphology may vary depending on substrate and environmental conditions. Some strains grow at 37°C. *P. zopfii* is the only unencapsulated species capable of growing at pH 5.1 in the presence of acetate (Pore 1985), or assimilating 1-propanol (Arnold and Ahearn 1972). Notably, only 80 percent of the strains tested grew in the presence of clotrimazole 50 μg/ml (Pore 1985), invalidating the use of clotrimazole for identification. No clinically derived strains of *Prototheca* spp. have been described as having a capsule, but spontaneous variants of *P. zopfii* in laboratory culture may produce a polysaccharide capsule; these variants are indistinguishable from *P. moriformis* by conventional morphological and physiological tests (Pore 1985). Several synonyms and varieties have been proposed for the pathogenic *Prototheca* spp., but *P. portoricensis, P. segbwema*, and *Portotheca salmonis* have been reduced to synonymy with *P. zopfii* (Pore 1998). Finally, an evaluation of morphological variability in *P. zopfii* was undertaken (Blaschke-Hellmessen et al. 1985).

CHLORELLA SPP.

In one report algae were isolated from cattle with lymphadenitis (Rogers et al. 1980) and in another from sheep liver (Zakia et al. 1989), but identification of genus and species was inconclusive. All other green algal infections were based on isolation or histopathological observations, and identification of species was not carried out. In previous taxonomic studies, identification of species followed the key points of Shihira and Krauss

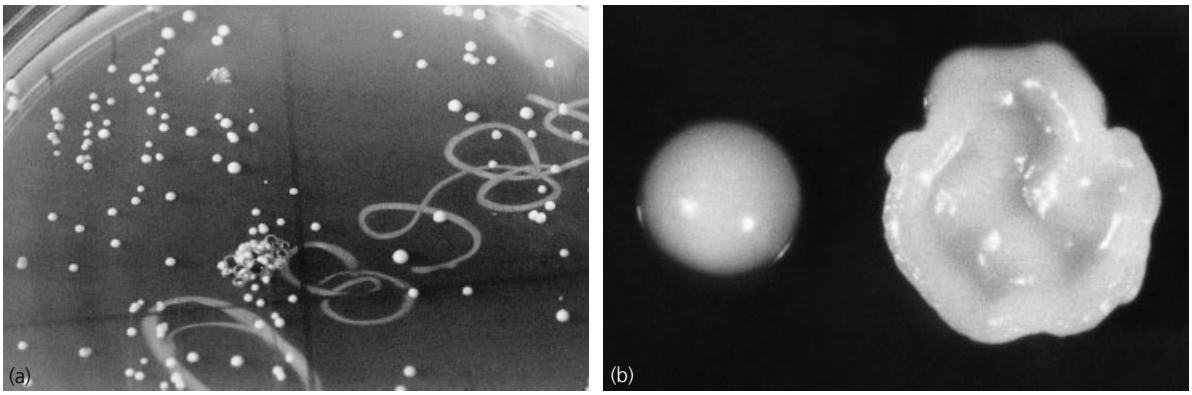

Figure 5 (a) *Primary isolation of* P. wickerhamii *from fecal (human) smear after 72 hours on PIM.* **(b)** P. wickerhamii *usually has a smooth, round colony after 72 hours on PIM:* P. zopfii *produces a larger wrinkled colony.*

(1965), who included *C. protothecoides*, the postulated extant ancestor of *P. wickerhamii,* as subsequent studies have shown (Pore 1998; Ueno et al. 2003). Except for the presence or absence of photosynthetic pigments, the physiological similarities, like the morphological similarities, between *C. protothecoides* and *P. wickerhamii* are remarkable. *C. protothecoides* even inhabits wastewater (Pore and Boehm 1986).

Histopathology

PROTOTHECA WICKERHAMII

P. wickerhamii may be rare to abundant in biopsied specimens of infected tissue, and histopathological detection is the usual means of diagnosis of protothecosis. The algal cells may be seen with the aid of H&E, Papanicolaou's, methylene blue, safranin, lactophenol cotton blue, or Gram's stains, but special stains, such as PAS and Gomori's methenamine silver (GMS), facilitate and confirm detection and identification (Figure 6). A comprehensive selection of color illustrations of the histopathology has been published

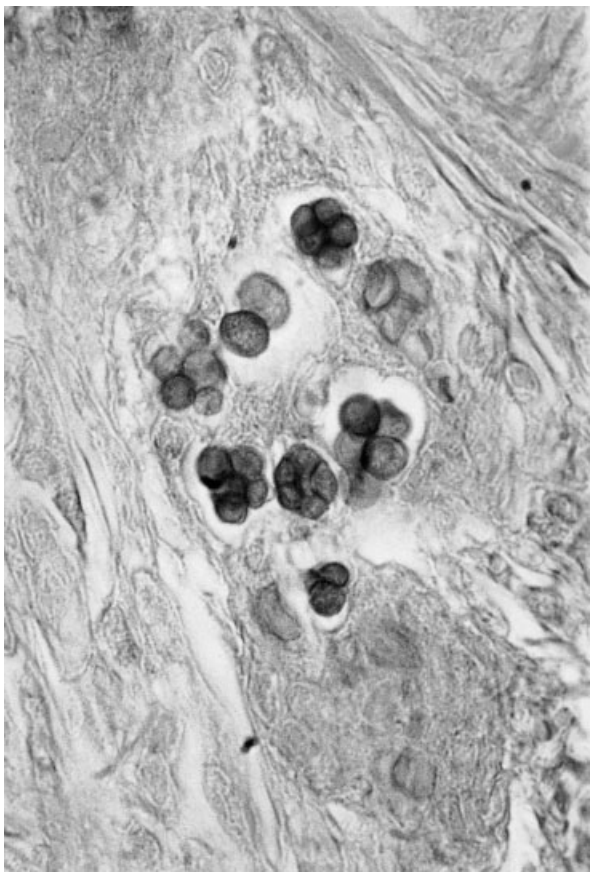

Figure 6 P. wickerhamii *in dermis stained by Gridley's silver stain method. In this instance the older sporangial walls are unstained and the sporangiospores alone are strongly stained. Magnification × 700*

(Chandler et al. 1980). Unlike in vitro size data, speciation on the basis of cell size in tissue is not definitive because of a size overlap of the sporangia of the two species, imprecise dating of the age of the algae, and the compounding influence of host tissue effects. Single cells range from 2 to 10 μm in diameter and sporangia from 10 to 30 μm, larger than in vitro sporangia and clearly overlapping the size range for *P. zopfii*. Empty, collapsed sporangia may be common, and could be difficult to differentiate from fungal debris. *P. wickerhamii* is unencapsulated; however, it was reported to stain weakly with mucicarmine (Kuo et al. 1987) – similar to the purported acid fastness; these may be staining artifacts, not observed by all investigators.

Infected epidermal and dermal responses include hyperkeratosis, parakeratosis, acanthosis, and papillomatosis (Davies et al. 1964). Granulomatous inflammatory reactions in the dermis and soft tissues were associated with multinuclear giant cells containing intracellular *P. wickerhamii*, a notable feature, and surrounded by lymphocytes, plasma cells, eosinophils, and a few polymorphonuclear leukocytes (Mars et al. 1971). Intraepidermal to mid-dermal depositions of the algae may be pathognomonic in cutaneous manifestations (Yip et al. 1976). *P. wickerhamii* may cluster in microabscesses, in which case the lesions show central necrosis and caseation. By contrast, other reporters have not always detected notable multinucleated giant cell response nor microabscess formation, but characterize the histopathological response as a mixed inflammatory response (Walsh et al. 1998).

The distinctive internal cleavage of the spheroidal sporangia, described as morula or being mulberry like, is considered pathognomonic for protothecosis; alternatively, sporangia that break open to release two to eight or more sporangiospores into the tissue are also indicative of *P. wickerhamii* (Figure 7). The sporangia are usually smaller, and the sporangiospores fewer and larger than those of *Coccidioides immitis* and *Rhinosporidium seeberi*. Juxtaposed algal cells of different sizes may falsely resemble budding, but a distinctive isthmus between two cells is never seen. Reports of internal starch granules and leucoplast lamellae are erroneous; *Prototheca* spp. have neither, although they do have refractive glycogen and lipid granules (unpublished observations).

Immunofluorescent reagents have led to a means for the histopathological identification of protothecosis and the differentiation of *P. wickerhamii* from *P. zopfii* (Sudman and Kaplan 1973). Many case reports would not have been published without the taxonomic corroboration obtainable with these serological reagents, but these reagents have limited availability and staining should be interpreted with caution. The best current method of speciation is still from the morphological and physiological traits of cultured isolates (see Table 2).

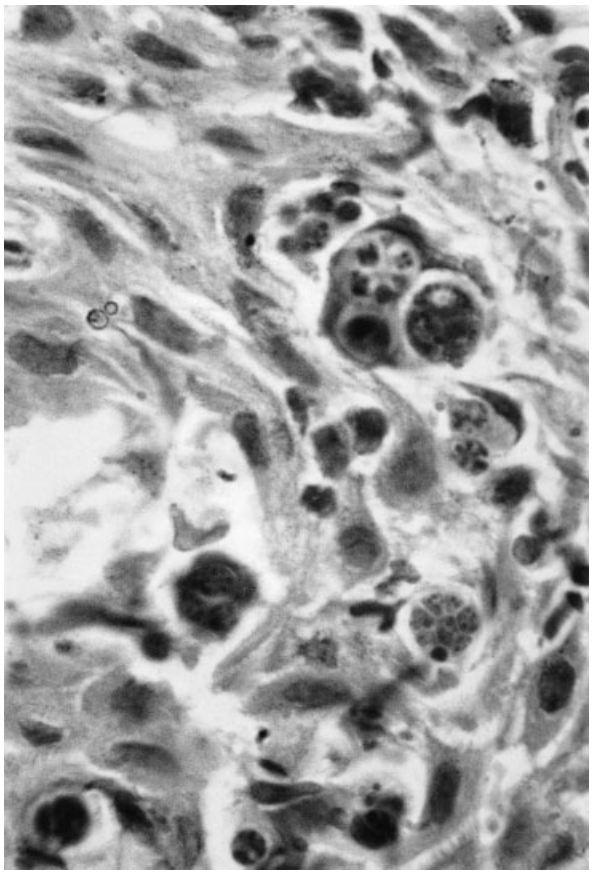

Figure 7 P. wickerhamii *in dermis with little tissue inflammation demonstrated by H&E staining. Several sporangia contain sporangiospores, the best histopathological identifying characteristic. Magnification × 700*

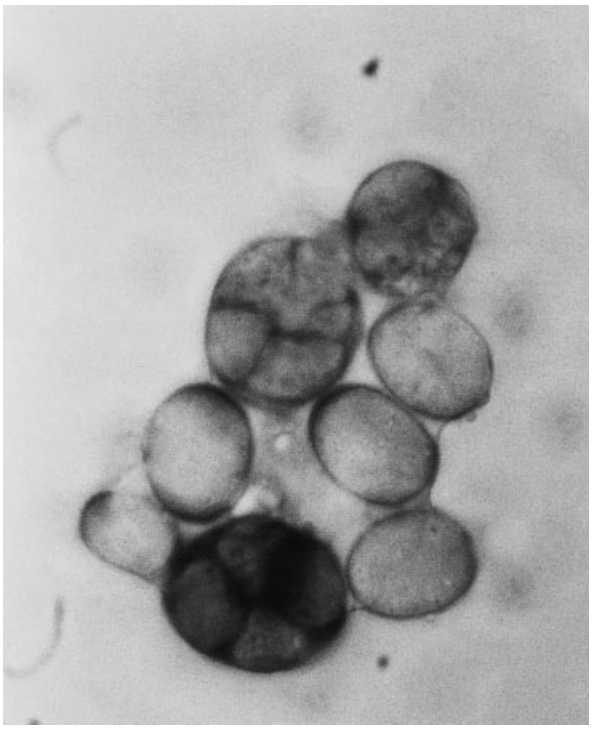

Figure 8 P. zopfii *is rare in secreted bovine milk without enrichment culture (see Table 1), but it is large and distinct when stained with methylene blue. Magnification × 700*

PROTOTHECA ZOPFII

P. zopfii causes chronic progressive pyogranulomatous lesions in the bovine mammary gland and associated lymph nodes. The microorganisms cluster in alveolar lumina and epithelia (Pore et al. 1987). They may also cause acute destruction of blood vessels, acini, and connective tissues in the udder, as well as mildly inflammatory, but highly destructive and necrotic, lesions of other organs (Taniyama et al. 1994; Jensen et al. 1998). The algal cells can be cultured from secreted milk (Figure 8). After experimental inoculation via the teat canal, living and degenerated *P. zopfii* cells were found in enlarged macrophages in granulomas, but not in associated neutrophils or epithelial cells (Cheville et al. 1984). Mastitis is almost solely caused by *P. zopfii*, whereas *P. zopfii* or *P. wickerhamii* causes dog infections equally frequently. Only three human infections with *P. zopfii* are known (Davies et al. 1964; Naryshkin et al. 1987; Kwok and Schwartz 1996); another was associated with a case of onycholysis (Magerman et al. 1991).

P. zopfii is unpigmented and the shrunken basophilic cytoplasm (seen by H&E staining) is within a large, unstained, spheroidal cell wall. However, the specific fungal stains, based on GMS or PAS, do stain the cell wall, even though the wall is chitin free. Specific immunohistochemical staining has helped to elucidate the intracellular sites of *P. zopfii* in macrophages and neutrophils from mastitic infections (Jensen et al. 1998; Corbellini et al. 2001a). Although cells resembling fungi may be seen, budding is absent and sporangial reproduction is present instead. All stages in the formation of two to six endospores are frequently seen within a sporangium after thin sectioning. In tissue, the sporangiospores of *P. zopfii*, but not the sporangia, are fewer and larger than those of *C. immitis* and *R. seeberi*. Although *P. zopfii* sporangia and sporangiospores are also larger than those of *P. wickerhamii,* in vitro, no comparable size data are available for the two species in histological material, so differentiation on the basis of size should be done with caution, if at all.

CHLORELLA SPP.

Histopathological identification to species or even genus is not possible among the small unicellular green algae. Green lymph nodes in sheep and cattle that histopathologically contain microorganisms resembling *Prototheca* or *Chlorella* spp. have been interpreted as chlorella infections based on the green appearance of these nodes (Chandler et al. 1980; Rogers et al. 1980; Jones et al. 1983; Connole 1990; Kaplan et al. 1993; Seniw et al. 1997). Reports of green tissues from animals are,

however, anecdotal and hard to interpret, and green lymph nodes have been found in a case of bovine protothecosis (Migaki et al. 1969). Chlorophyll is soluble in alcohol and absent from most histopathological preperations. In at least one instance, however, the infectious microorganisms contained electron microscopic evidence of chloroplasts (Kaplan et al. 1993) – definitive evidence of a green alga, although not necessarily *Chlorella* spp., but conclusive evidence that the microorganisms were not *Prototheca* spp. Finally, not all *Chlorella* spp. contain starch granules as is sometimes erroneously reported; *C. protothecoides* is such an example. *C. protothecoides* is an alga that stores glycogen, as does *Prototheca* spp. (unpublished observations). Many other *Chlorella* spp. species do store starch, and such PAS-stainable granules in the cytoplasm may after all prove to be an identification characteristic (Chandler et al. 1980).

Pythiosis

LEONEL MENDOZA

History	1	Clinical and pathological signs of infections caused by *Pythium insidiosum*	7
Taxonomy and morphological features of *Pythium insidiosum*	2	Immunology	10
Epidemiology	5	Laboratory diagnosis	11
Distribution	6	Treatment	14
Life cycle of *Pythium insidiosum*	6	References	16

Members of the oomycetous genus *Pythium* are ecologically and physiologically unique. They occur in soil and aquatic habitats worldwide. *Pythium* species are important plant pathogens causing seed decay, preemergent and post-emergent damping off, root rot of seedlings, and rot of stored foodstuffs. In addition, some species of *Pythium* have been reported to cause disease in fish. *Pythium insidiosum*, however, is the only member of the genus that has been recognized as a mammalian pathogen. Chandler et al. (1980) coined the term pythiosis to include all clinical and pathological manifestations caused by *P. insidiosum* in mammals. In horses, the disease has been long known as bursatee, leeches, granular dermatitis, hyphomycosis destruens equi, phycomycosis, espundia, summer sores, and swamp cancer. Pythiosis in mammals is characterized by the development of cutaneous, subcutaneous, blood vessel, and intestinal lesions and, less frequently, by the involvement of bones and lungs. If not treated, the disease progresses rapidly, becoming life-threatening.

HISTORY

The first reported cases of equine pythiosis were described in the middle of the last century when veterinarians studied cutaneous granulomas among equines in India. The etiology of the disease was not established. The first well-documented cases, in which the 'fungal-like' nature of the infection was suggested, were those published by Smith (1884), Fish (1895–96), and Drouin (1896). In Indonesia, de Haan and Hoogkamer (1901), working with several equines with cutaneous granulomas, isolated the etiologic agent of pythiosis for the first time. Their isolate, however, could not be identified because it did not sporulate on their media. These investigators named the disease hyphomycosis destruens. This name was modified later by de Haan (1902) to hyphomycosis destruens equi. In 1924 another Dutch scientist, working with horses in Indonesia, completed the most comprehensive papers on equine pythiosis ever published (Witkamp 1924, 1925). He also isolated a nonsporulating organism from equine cutaneous granulomas and covered several aspects of the disease, including its clinical signs, pathology, microbiology, animal inoculation, diagnosis, treatment, and immunology. Unfortunately, this classic work remained largely unnoticed, in part because of its Dutch language, but also because of the contemporaneous finding that cutaneous granulomas in horses may also be caused by nematode species of the genus *Habronema* (Ransom 1911). Thus, the terms used to describe pythiosis were also indiscriminately used for equine cutaneous habronemiasis.

The early findings on the 'fungal' nature of cutaneous granulomas in equines were obscured by the new

hypothesis of equine habronemiasis, and the presumed mycotic etiology was forgotten. Thirty-seven years later, Bridges and Emmons (1961) isolated a sterile, filamentous microorganism from equine cases in Texas and Florida, similar to those that had been studied by de Haan and Hoogkamer and Witkamp earlier in the century. They believed that they had isolated 'a species of *Mortierella*' – a zygomycete. The filamentous isolate was named *Hyphomyces destruens*, based on the disease name previously coined by de Haan and Hoogkamer (1901, 1903). It was not clear, however, if the authors intended to introduce a new binomial for the etiologic agent of cutaneous granulomas in horses. In 1974, Austwick and Copland reported that an organism, isolated from horses in Papua New Guinea afflicted with swamp cancer, formed biflagellate zoospores after transfer to a petri dish of sterile water to which a sterilized decayed piece of rotten maize silage had been added. They concluded that the organism should be classified in the oomycete genus *Pythium* but they failed to provide a scientific name for their isolate.

Later, Ichitani and Amemiya (1980) isolated a filamentous microorganism from a Japanese horse with granular dermatitis. Based on the production of smooth oogonia and aplerotic oospores, they identified their isolate as *Pythium gracile*. In 1987, de Cock et al., working in Costa Rica with numerous isolates of a *Pythium* sp., recovered from horses that had espundia (a regional name used for pythiosis), concluded that these isolates belonged to an undescribed species of *Pythium* and the binomial *P. insidiosum* was validly introduced. They also reported that other isolates from cows, dogs, horses, and humans, including the one described as *P. gracile*, also belonged to the single species *P. insidiosum*. Almost concurrently an isolate, from horses in Australia, was also described as a new species and named *Pythium destruens* by Shipton in 1987. Later this isolate was studied by Mendoza and Marin (1989) and it was found to be indistinguishable from the strains isolated from other pythiosis cases; it thus became a synonym for *P. insidiosum*. Recently, Schurko et al. (2003a, b), using molecular tools, confirmed that *P. insidiosum* is the only etiologic agent in the genus causing pythiosis in mammals.

Since 1961 several new cases of pythiosis have been reported in equines (Habbinga 1967; Hutchins and Johnston 1972; Connole 1973; McMullan et al. 1977; Murray et al. 1978; Miller and Campbell 1982b; Mendoza and Alfaro 1986), cats (Bissonnette et al. 1991; Thomas and Lewis 1998), cattle (Miller et al. 1985; Santurio et al. 1998), dogs (Pavletic et al. 1983; Foil et al. 1984; Thomas and Lewis 1998; Graham et al. 2000), humans (Thianprasit 1986, 1990; Rinaldi et al. 1989; Sathapatayavongs et al. 1989; Chetchotisakd et al. 1992; Triscott et al. 1993; Virgile et al. 1993; Imwidthaya 1994b), and in captive bears and a camel in South Carolina and Florida zoos respectively (personal communications, L. Kaufman and A.A. Padhye, and J.F.X. Wellehan).

TAXONOMY AND MORPHOLOGICAL FEATURES OF *PYTHIUM INSIDIOSUM*

Pythium insidiosum is an organism classified in the kingdom Straminipila, class Oomycetes, order Pythiales, and family *Pythiaceae* (Dick 2001). Although Dick (2001) suggests the term Peronosporomycetes to rename the class Oomycetes in the kingdom Striminipila, for convenience, we will continue using the term Oomycetes throughout this chapter. This was motivated also by his position to treat the straminipilans as members of the kingdom Fungi. In recent years, however, strong phylogenetic evidence has been generated indicating that the straminipilans are not fungi, but protistal microbes very close related to algae and plants (Herr et al. 1999; Baldauf et al. 2000). Patterson in 1989 proposed the term Stramenopila. This name has been widely used. However, Dick (2001) recently modified it to Straminipila. He stated that the term Stramenopila is a bad derivation from the latin 'stramini'= a straw and 'pilus'= a hair. So, the straminipilans are organisms bearing tubular tripartite hairs. Therefore, the right spelling of this term should be Straminipila. Dick (2001) also indicated that the spelling 'straminopile,' appearing in the *Dictionary of fungi* (Hawksworth et al. 1995), was an unintentional misprint corrected in the 2001 edition of the same dictionary (Kirk et al. 2001).

In culture, *P. insidiosum* develops fungal-like sparsely septate hyphae; thus it erroneously has been referred to as a microorganism belonging to the kingdom Fungi. All of its phylogenetic features, however, correlate with the kingdom Straminipila (Baldauf et al. 2000; Martin 2000; Dick 2001). On this basis, *P. insidiosum* should only be referred to as a protist or a parafungal organism. As with other oomycetes, *P. insidiosum* grows relatively well on a variety of media. On cornmeal agar, colonies are colorless to white and submerged, with short aerial filaments, and a finely radiate pattern. The hyphae range between 4 and 10 μm in diameter with perpendicular lateral branches. Cross-septa are only occasionally observed in young hyphae, but they are abundant in old viable hyphae. Appressoria and hyphal swellings, measuring 12–28 μm in diameter, are common in laboratory cultures (Figure 1a, b).

Production of zoosporangia is only possible in water cultures incubated at 28–37°C. Zoosporangia increase in number when *P. insidiosum* is placed in contact with pieces of grass leaves in water containing a minimal quantity of different ions (including Ca^{2+}) (Mendoza and Prendas 1988). Early-stage sporangia cannot be differentiated from vegetative hyphae. At maturity, sporangial protoplasm flows into a discharge tube and

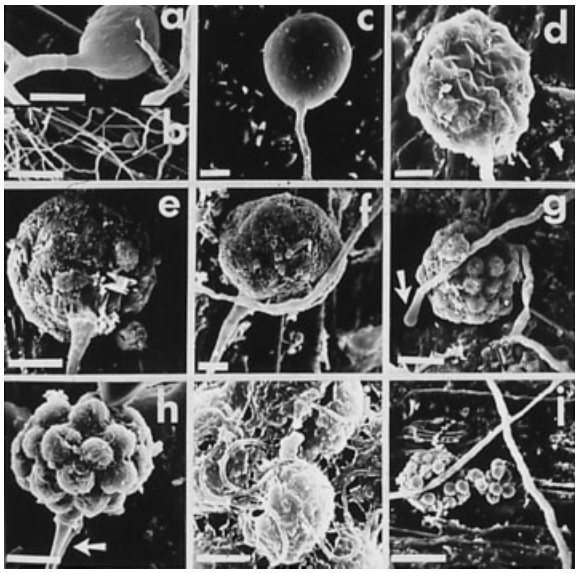

Figure 1 *Transmission electron microscopy of* Pythium insidiosum*'s different stages of development. The formation of globose vesicles and hyphae on a leaf are the first steps in the colonization of a plant host (a, b). The electron photographs show sporangial formation leading to the release of secondary-type zoospores (c–j). Bar:* **(a, c)** *28 μm,* **(b)** *120 μm,* **(d)** *20 μm,* **(e)** *30 μm,* **(f)** *15 μm,* **(g)** *32 μm,* **(h)** *18 μm,* **(i)** *15 μm,* **(j)** *50 μm. (Reproduced, with permission, from Mendoza et al. 1993)*

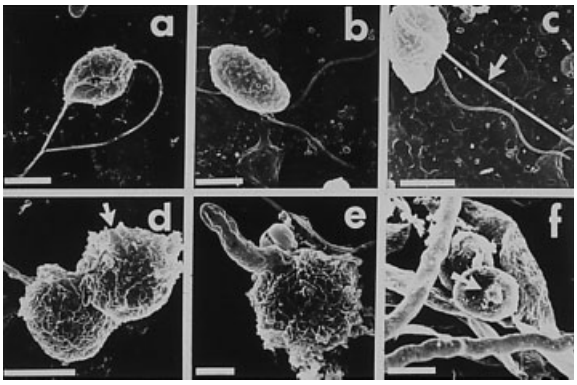

Figure 2 *Transmission electron microscopy of* Pythium insidiosum*'s motile zoospores (a–c). Encysted zoospores are characterized by their globose morphology (d–f). Arrows indicate the place once occupied by the flagella. An amorphous substance used to bind the zoospores to the host's tissue is evident over the surface of encysted zoospores. Zoospores that encyst away from leaf or animal tissues do not secrete this amorphous material* **(f)**. *Bars:* **(a, b)** *9 μm,* **(c, d, f)** *10 μm,* **(e)** *5 μm. (Reproduced, with permission, from Mendoza et al. 1993)*

forms a vesicle. It is globose and hyaline, and measures 20–60 μm in diameter. Through progressive cleavage, biflagellate zoospores are formed inside the vesicle (Figure 1c). The internal developmental process within the undifferentiated vesicle and the release of zoospores takes about 35 minutes. The zoospores mechanically break the vesicle's wall and upon emergence swim for about 20 minutes and then encyst (Figure 1j). The zoospores are reniform and of the secondary biflagellate type. The two flagella arise from the deeper part of a lateral groove and seem to emerge from a common point. They are unequal in length. The anterior shorter flagellum is of the tinsel type and is covered with mastigonemas (small hair-like structures). The posterior flagellum is of the whiplash type and lacks mastigonemas (Figure 2a–c). After encystment, the zoospore's flagella are detached and it becomes spherical. When chemotactically stimulated by a suitable substrate (plant or animal tissue), the zoospores secrete anamorphous sticky material which covers their surface, and they become attached to the plant's or animal's surface. This substance, which may be a glycoprotein, has been implicated as a potential virulence factor in establishing infection (Mendoza et al. 1993) (Figure 2d–f).

In contrast to other species of the genus, only a few strains of *P. insidiosum* have been reported to produce oogonia. Thus, the mechanism implicated in the process of oogonial formation in *P. insidiosum* remains obscure. When oogonia develop in vitro, they are intercalary, smooth, and subglobose. They have a rigid fertilization tube measuring 23–30 μm in diameter and may have one to three declinous antheridia per oogonium. The antheridia are attached over their entire length to the oogonium (de Cock et al. 1987; Shipton 1987). The oospores are aplerotic, or almost plerotic, and are pressed to one side of the oogonium by the rigid fertilization tube. They measure 20–25 μm in diameter (Figure 3k) (de Cock et al. 1987; Shipton 1987). The morphology of the mature oogonia is the basis for speciating members of the genus *Pythium*.

Schurcko et al. (2003a, b) using phylogenetic tools, reported that in the analyses done on 23 isolates of *P. insidiosum* from the Americas, Asia, and Australia, all clustered together according to their geographical areas (Figure 4). This study showed that *P. insidiosum* is more closely related to each other than to any other *Pythium* species, and quite different from the genera *Phytophthora* and *Lagenidium*. Interestingly, the third cluster of *P. insidiosum* strains was made of isolates from Thailand and the USA. Schurcko et al. (2003b) suggested that these unique isolates could belong to new species very close related to *P. insidiosum*. However, they did not treat these cryptic variants as such.

Recently, Grooters (2003) found that clinical cases initially thought to be pythiosis in dogs were not caused by *P. insidiosum*, but by a new species in the genus *Lagenidium*. She based her findings on morphological and molecular studies. In a recent phylogenetic study, however, Schurko et al (2003a, b) described at least three cryptic strains of *P. insidiosum*. These strains formed a sister clade with the other 20 *P. insidiosum* isolates studied by them. They stated that all *P. insidiosum*, and the other *Pythium* spp, were closer to the

genus *Lagenidium* and far away from the genus *Phytophthora*. Thus, it could be that the strains studied by Grooters (2003) may be related to the third group described by Schurko et al (2003a, b) rather than being new members of the genus *Lagenidium*. However, this conjecture needs verification.

EPIDEMIOLOGY

Pythium spp. are ecologically versatile microorganisms. They occur in practically all soils and wet environments. They are among the most destructive phytopathogens, inflicting economic losses on a wide variety of crops. However, of all the described species (about 120) only one, *P. insidiosum*, has been implicated as an etiologic agent of mammalian disease. Since the last century, water has been related to cases of cutaneous granulomas in equines. It was noted that, after horses had grazed for a lengthy period in stagnant water, they frequently developed pythiosis. The term 'bursattee,' derived from the Indian words 'bururs' or 'bursat,' meaning rain or rain sore, was used in India to describe this condition. Moreover, equine pythiosis has been referred to as swamp cancer in some areas of the world. Thus, a relationship between wet habitats and this disease had been suspected from early in its history. In Australia, equine pythiosis is usually observed in late summer and autumn after the formation of large bodies of stagnant water from the remnants of the previous winter's rains and high seasonal temperatures – conditions that favor the rapid growth of *P. insidiosum* (Miller and Campbell 1982b; Shipton 1985). Miller (1983) noted that, under laboratory conditions, the zoospores of *P. insidiosum* are attracted to animal hair and tissue. He used horse hair as bait to isolate *P. insidiosum* from swampy areas in Australia. He speculated that this oomycete lives in wet habitats and that perhaps it may require a plant to complete its life cycle. Although an unidentified water lily was suggested as a possible plant host (Miller 1983), other findings (Mendoza and Prendas 1988; Chaiprasert

et al. 1990; Mendoza et al. 1993) indicate that, during its life cycle, *P. insidiosum* may preferentially use grass tissue, but in environments free of gramineae, it may complete its life cycle on other plants.

DISTRIBUTION

Pythiosis is a disease of the temperate, subtropical, and tropical areas of the world. It has been reported in Argentina, Australia, Brazil, Colombia, Costa Rica, Haiti, India, Indonesia, Japan, New Guinea, New Zealand, South Korea, Thailand, the USA, and Venezuela. Verified cases of this disease have not been reported in Europe. A case of cutaneous granulomas in a horse with all the features of pythiosis was, however, published by Drouin (1896) in France. The geographical location and tropical climate of Africa seemingly would make it an ideal region for pythiosis. Nevertheless, cases from that continent have yet to be reported. In the Americas, the disease has been diagnosed in North, Central, and South America, as well as the Caribbean islands.

In the USA, the disease is more common in states near the Gulf of Mexico: Alabama, Florida, Louisiana, Mississippi, and Texas. In addition, sporadic cases have been diagnosed in nearby states such as Georgia, Missouri, North Carolina, South Carolina, Tennessee, and as far off as Illinois, Indiana, New York, and Wisconsin – all temperate regions of the USA near the Canadian border. Cases of pythiosis have not as yet been described from Mexico. In Central America, Costa Rica is the country with the largest number of documented cases of pythiosis in horses. This disease is most prevalent in the Atlantic region. Some cases have been diagnosed along its Pacific coast, however. The disease has been observed in other Central American countries – Guatemala, Nicaragua, and Panama (personal communications), but there are no recorded cases in the literature. In the Caribbean region, a case of human pythiosis was recently recorded in Haiti, so the disease may also be present in the other islands of that tropical region (Virgile et al. 1993). Northern Argentina, Brazil, Colombia, and Venezuela have reported cases of equine pythiosis since 1965. The Pantanal region of Brazil, the world's largest freshwater wetland, may have the highest incidence and prevalence of equine pythiosis, but systematic studies are not available to support this impression (dos Santos and Londero 1974; Santurio et al. 1998; Leal et al. 2001).

Australia, the Pacific islands, and Asia have reported cases of pythiosis since the last century. In Australia, it has been found in Maitland, New South Wales, the coast of Queensland, the Northern Territory, and Western Australia. In Indonesia, the disease occurs in Borneo, Java, and Sumatra. In Japan, pythiosis is known to occur along the southern coast of Kyushu and the Ryukyu Islands. A case of intestinal pythiosis was recently reported in a dog from South Korea, suggesting that the disease could also be present in North Korea and China (Sohn et al. 1996). In Thailand, cases of human pythiosis have been found in the northern and southeastern parts of the country. Figure 5 shows the currently known distribution of pythiosis around the world.

LIFE CYCLE OF *PYTHIUM INSIDIOSUM*

P. insidiosum, as with other *Pythium* spp., is an organism of aquatic environments, although it can also be found in soil as a result of its ability to produce resistant spores (de Cock et al. 1987; Mendoza et al. 1993). To maintain its life cycle in nature, *P. insidiosum* requires a low concentration of ions, a pH near neutrality, and a plant host (Shipton et al. 1982; Shipton

Figure 5 *Map showing the distribution of pythiosis in the tropical, subtropical, and temperate regions of the world.*

1983, 1985). As for other zoosporic fungal-like organisms (Endo and Colt 1974), *P. insidiosum* probably uses plants to produce sporangia and release zoospores to colonize other plants and expand its ecological niche, but it has not been demonstrated to cause pathology in plants. Early studies on the life cycle of this oomycete have shown that *P. insidiosum* is present in stagnant waters and may possibly require the Australian water lily or other plants to complete its life cycle (Miller 1983). It was also found that its zoospores may play an important role in the propagation of infections among plants and animals. More recently, other investigators (Mendoza et al. 1993) confirmed that *P. insidiosum* has a special tropism for animal and plant tissues, and that, upon release of zoospores, several mechanisms are activated that permit plant and animal tissue invasion. Encysted zoospores are surrounded by an amorphous material that has adhesive properties. This substance attaches the zoospores to the host's surface. They further hypothesized that chemotactic factors may signal zoospores to produce this material. Figure 3 illustrates various stages of *P. insidiosum*'s life cycle in detail.

CLINICAL AND PATHOLOGICAL SIGNS OF INFECTIONS CAUSED BY *PYTHIUM INSIDIOSUM*

The pathogenesis of pythiosisis not clear, in part because the disease is not reproducible in natural hosts. Laboratory data obtained from strains of *P. insidiosum* indicated that zoospores have a tropism for animal and plant tissues (Miller 1983; Mendoza et al. 1993). Thus, the zoospores, as motile propagules, in all likelihood, play a role as infecting agents in natural infections. However, reports of pythiosis in animals and humans with no history of contact with stagnant water open the possibility of inoculation by other propagules of *P. insidiosum* (hyphae, resting spores, oogonia) (Rinaldi et al. 1989; Fischer et al. 1994).

When an animal or human enters swampy areas inhabited by *P. insidiosum*, its zoospores would be attracted by any open wound on their skin and encyst on the exposed tissue. On the basis of electron microscopic observations (Mendoza et al. 1993), the zoospores are known to secrete a sticky substance that allows them to make and maintain tight contact with the host during the initial stages of invasion. Stimulated by the temperature of the host's skin, the encysted zoospores develop a germ tube, often directed towards injured tissue (Mendoza et al. 1993), and mechanically penetrate the tissue (see Figure 2e). Ravishankar and Davis (2001) experimentally established that *P. insidiosum* cannot penetrate normal skin, but has the potential to successfully penetrate injured skin. Their study strongly supports previous speculations. *P. insidiosum* initiates a cell-mediated immune response in its host, mostly in the form of eosinophils and a few neutrophils (Miller and Campbell 1983; Mendoza and Alfaro 1986), but the immune response cannot prevent the propagation of *P. insidiosum*. The eosinophils then, in an effort to phagocytose the microorganism, degranulate over the hyphae. New eosinophils fuse around the degranulated eosinophils and are also degranulated in turn. A mass known as a 'kunker' is thus formed. The eosinophilic material (Splendore–Hoeppli-like phenomenon) around *P. insidiosum* hyphae is a main feature of the infection in equines but not in the other species. Kunkers are composed of degranulated eosinophils interlaced with the viable hyphae of *P. insidiosum*. The lower panel of Figure 3 summarizes the probable mechanism of infection. The tissue damage observed in acute and chronic cases has been attributed to the release of chemicals from the degranulated eosinophils and mast cells (Miller 1981; Miller and Campbell 1983; Mendoza et al. 2003).

Pythiosis in non-primates

HORSES

Since the beginning of this century, the clinical features of pythiosis in horses have been well described by several authors (de Haan and Hoogkamer 1901, 1903; Witkamp 1924; Bridges and Emmons 1961; McMullan et al. 1977; Miller and Campbell 1982b; Chaffin et al. 1995). There are no reports of predisposition with regard to sex or age of the afflicted animals. Lesions caused by *P. insidiosum* are found on any part of a horse's body, although they are more common on the lower limbs because these are the first areas to come in contact with swampy water. In addition, the lesions in horses can also be found on the thorax, abdomen, neck, shoulders, genitalia, and head. Pythiosis often occurs as a single lesion but unusual cases with multicentric granulomas have been encountered. When lesions develop on the extremities (particularly near the joints), lameness is a frequent finding. In chronic pythiosis, emaciation and secondary infections are also common. There are no reports of animal-to-animal, or animal-to-human transmission of infection.

Lesions are circular in shape, from 5 to 500 mm in diameter (Miller and Campbell 1982b; Mendoza and Alfaro 1986), with a characteristic serosanguineous discharge (Figure 6a, b). Intense pruritus is one of the characteristic clinical features of the disease in horses. Ulceration of the tissue is common in large lesions. Smaller ones often show one or more small ulcers. As the disease progresses, small coral-like masses called kunkers, which contain viable hyphae of *P. insidiosum*, are found in the sinuses and surface of the infected tissue. They vary in size and form (10–90 mm in diameter) (Figure 7). Metastasis of *P. insidiosum* through lymphatic vessels to regional lymph nodes (Connole 1973; Murray et al. 1978), lungs (Witkamp

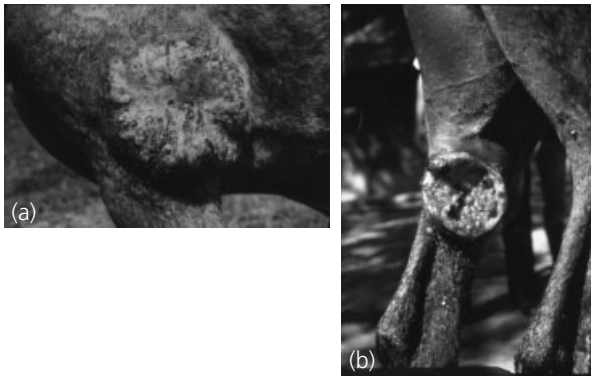

Figure 6 *Clinical features of cutaneous granulomas caused by* Pythium insidiosum *in two horses (a, shoulder; b, leg). Note the circular shape typical of pythiosis granulomas in horses.*

1924; McMullan et al. 1977; Goad 1984), or bones (Mendoza et al. 1988; Alfaro and Mendoza 1990; Eaton 1993; Neuwirth 1993) is common (Figure 8). Equine intestinal pythiosis, resulting from direct inoculation of propagules of *P. insidiosum* in mucous membranes, has been reported (Brown and Roberts 1988; Morton et al. 1991; Purcell et al. 1994).

Histopathologically, in the early stages of pythiosis, abundant microabscesses with an inflammatory reaction, composed mainly of eosinophils, a few neutrophils, lymphocytes, and macrophages, are present in the subcutaneous lesions. In chronic cases, eosinophilic granulomatous tissue with giant cells is often recorded. In central areas of inflammation, sequestered eosinophilic masses (kunkers) are detectable. Sections of the kunkers stained with Gomori's methenamine silver reveal the presence of aseptate hyphae 6–10 μm in diameter along with cellular debris (Figure 9).

DOGS

Canine infections were first reported in dogs with cutaneous and gastrointestinal lesions from the Gulf of Mexico in the USA (Heller et al. 1971; Miller et al. 1983; Pavletic et al. 1983; Foil et al. 1984). Subcutaneous pythiosis lesions have been recorded also on the legs, face, and tail in dogs (Figure 10) (Foil et al. 1984; Thomas and Lewis 1998). Systemic pythiosis with involvement of internal organs has also been reported in dogs (Foil et al. 1984; Thomas and Lewis 1998). The pruritic

skin lesions were denuded of hair and perforated by fistulous sinus tracts discharging a serosanguineous exudate. Histopathological findings included multifocal areas of necrosis with moderate neutrophils and macrophages. Discrete granulomatous infiltrates with eosinophilic material are surrounded by eosinophils, neutrophils, and epithelioid cells. Giant cells have also been reported in chronic cases. Hyphae which measured 4.4–8.6 μm in diameter were detected in these tissues.

Gastrointestinal pythiosis in dogs is characterized by vomiting, weight loss, and sporadic diarrhea (Miller et al. 1983, 1985; Pavletic et al. 1983; Thomas and Lewis 1998). Formation of hard gastrointestinal granulomatous masses, areas of mural thickness, and mucosal ulceration are common in most cases. Lesions can spread to adjacent tissue such as that of the pancreas, uterus, and mesenteric lymph nodes. Histopathologically, the mucosa shows ulceration, atrophy, and epithelial cell hyperplasia. The submucosa is thickened and the muscular mucosa contains focal granulomas. Neutrophils, eosinophils, plasma cells, macrophages, epithelioid cells, and giant cells are observed in the affected tissues. The hyphae of *P. insidiosum* are difficult to detect in hematoxylin–eosin-stained sections, but with Gomori's methenamine silver stain, hyphae between 2.5 and 8.9 μm in diameter are readily detected. Recently, cases of canine pythiosis have been recorded in Australia (English and Frost 1984) and in the USA (Miller et al. 1985).

Grooters (2003) stated that there were clinical cases similar to those observed in canine pythiosis, caused by an undescribed species in the genus *Lagenidium*. She based her findings on histopathological, cultural, and molecular analysis. However, her data have yet to be confirmed by others (see earlier under Taxonomy and morphological features of *Pythium insidiosum*).

Cats and cattle

Few cases of pythiosis in cats (Bissonnette et al. 1991; Thomas and Lewis 1998) and calves (Miller et al. 1985; Santurio et al. 1998) have been described in the literature. Bissonnette et al. (1991) was the first to diagnose a case of pythiosis in a cat with facial swelling, but none of its internal organs was involved (Figure 11a). *P. insidiosum* was isolated from the affected tissue. Histopathological features, similar to those recorded in horses and dogs, were observed in this case.

A total of five calves with pythiosis have so far been reported with the disease. Showing multiple focal ulcers and fistulous tracts, draining a watery purulent exudate and with swelling of fetlock joints, they were diagnosed with pythiosis (Miller et al. 1985; Santurio et al. 1998). Miller and colleagues (1985) reported that *P. insidiosum* was isolated from two of the studied calves, whereas *P. insidiosum*-like hyphae were found in the tissue of a third case. Histological sections from that case showed granular encrustations around the hyphae. The perihyphal deposit was composed of granular material similar to that of the Splendore–Hoeppli phenomenon. Similar observations were described by Santurio et al. (1998) in calves from the Pantanal region of Brazil.

More recently, several cases of pythiosis in calves were also described in the State of Apure, Venezuela (Figure 11b) (personal communication, Rosa Cristina Perez). Serological testing done in these animals was consistent with *P. insidiosum*. In addition, histopathological and DNA sequencing analysis from the infected tissues confirmed the presence of this pathogen in the infected calves.

Human pythiosis

Most human cases have occurred in Thailand with only a few reports of such cases in Australia, Haiti, New Zealand, and the USA. Two human cases of subcutaneous pythiosis were mentioned by de Cock et al. (1987), but details about those early cases were not available. The first five cases of this disease in humans involved two women and three men in the rural areas of northern Thailand (Sathapatayavongs et al. 1989). Ten

Figure 11 (a) *Lesions on a cat from Florida, USA with subcutaneous pythiosis (arrow).* **(b)** *A subcutaneous lesion on the limb of a Venezuelan calf caused by* Pythium insidiosum. *(Courtesy of Dr Randall C. Thomas and Rosa Cristina Perez)*

more cases were later reported from the same areas of Thailand (Chetchotisakd et al. 1992; Wanachiwanawin et al. 1993). Most were associated with a hemoglobinopathic syndrome. Clinically, progressive gangrene and pain in the extremities were the main findings. Strikingly, all cases showed large vessel arteritis (Figure 12). Angiographic analysis indicated occlusion of the iliac, popliteal, and femoral arteries. Treatment by amputation was successful in seven of the 15 cases. Fatal invasion of the abdominal arteries with occlusion of the infrarenal part of the aorta was also recorded. So far, the majority of cases of human pythiosis have occurred in Thailand, with some 90 new patients reported since the first case in 1987 (personal communication, Theerapong Krajaejun).

Three patients with subcutaneous orbital pythiosis were diagnosed in the USA (Rinaldi et al. 1989). One was a healthy boy in Texas who had accidentally been struck in his right eye. He developed progressive peri-

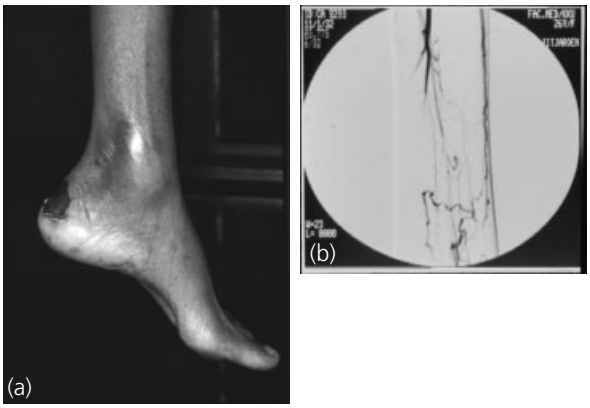

Figure 12 (a) *Dry gangrenous lesion on the left leg caused by* Pythium insidiosum *in a Thai thalassemic patient.* **(b)** *Digital subtraction angiography of the same patient showing occlusion of the left superficial femoral artery. (Courtesy of Dr Ploenchan Chetchotisalkd, Thailand)*

orbital oedema with chemosis, erythema, and periorbital cellulitis (Figure 13). *P. insidiosum* was isolated from biopsied tissue. Details of the second case were not discussed. The third case was recorded by Shenep et al. (1998) on a 2-year-old boy from Tennessee. Two additional cases of pythiosis with a similar clinical history were reported in Australia (Triscott et al. 1993). These cases involved an 11-year-old and a 14-year-old boy. Both developed periorbital swellings which rapidly developed into an orbital tumour. The diagnosis was made histopathologically using an immunoperoxidase staining assay (see section on Immunohistochemical assays below). In addition to vessel arteritis and subcutaneous pythiosis in humans, cases of keratitis have also been recorded in Haiti (Virgile et al. 1993), New Zealand (Fraco and Parr 1997), and Thailand (Kunavisarut et al. 1988; Imwidthaya and Methitrairut 1992; Imwidthaya 1995).

Triscott et al. (1993) described in detail the histopathology of subcutaneous pythiosis in humans. They found that the histological features were similar to those of equine pythiosis. Eosinophilic granular masses of about 7 mm in diameter, containing degenerating eosinophils, eosinophilic granules, hyphae, and intact eosinophils at the edge of the granulomatous areas were the main findings. They also reported a mixed inflammatory cell infiltrate comprising eosinophils, lymphocytes, neutrophils, macrophages, and mast cells. As in equine pythiosis, the hyphae of *P. insidiosum* were restricted to the areas of the eosinophilic granular masses. Kunkers, as recorded in equine pythiosis, have not, however, been detected in tissue from human cases.

IMMUNOLOGY

The development of an immune response to *P. insidiosum* antigens during equine infections has been known since early in the century (Witkamp 1924, 1925).

Figure 13 *Severe orbital swelling resulting from* Pythium insidiosum *infection in a healthy boy. (Courtesy of Drs Michael G. Rinaldi and Steven Seidemseld, USA)*

In those studies, Witkamp described precipitin and complement fixation antibodies, and a cellular immunity response to a skin test in horses with active pythiosis. Miller and Campbell (1982a), using a similar approach, confirmed this early work. At least three antigens were prepared. A trypsin–hyphal antigen detected one precipitin band by double immunodiffusion (ID) in all horses with the disease. By contrast, only 82 percent of the horses were positive to a complement fixation test. The skin test, using a precipitate protein antigen, was positive in 64 percent of the clinically infected horses and in 31 percent of normal horses inhabiting the enzootic areas. The finding that normal animals reacted positively in a delayed hypersensitivity skin test indicates that subclinical pythiosis may occur in some horses. They also reported detectable levels of *P. insidiosum* antibodies at the day of birth in foals born to mares with active pythiosis, suggesting that their foals received some degree of passive immunity against *P. insidiosum*. Horses with a history of pythiosis but negative to skin tests were considered anergic. Analogous immunological studies in other areas also confirmed these findings (Mendoza and Alfaro 1986; Grooters et al. 2002; Krajaejun et al. 2002).

Immunization (immunotherapy) with antigens derived from *P. insidiosum* was shown to have curative properties in horses afflicted with the disease (Miller 1981; Mendoza and Alfaro 1986; Hensel et al. 2003; Mendoza et al. 2003). Fifty percent of infected horses responded to immunization. Changes from an eosinophilic infiltrate, before immunization, to a mononuclear response (macrophages, T lymphocytes), after immunization, suggested that cellular immunity was playing a major role in the clearance of *P. insidiosum* from immunized horses. Mendoza et al. (2003) suggested that a switching from a T helper 2 (Th2) to a T helper 1 (Th1) response was behind the curative properties of the immunotherapeutic antigens used by these investigators.

Animals in the early stages of pythiosis react positively to a delayed hypersensitivity skin test using a culture filtrate antigen (CFA) and are cured by immunization with precipitated protein antigens. These observations, together with the fact that sera from humans and animals reacted positively in ID and Western blot tests, indicated that cellular and humoral immunity were active in the early stages of the disease. Animals became anergic when the disease reached chronicity (>2 months).

Systemic human pythiosis in Thailand, on the other hand, has been diagnosed mainly in thalassemic patients (Imwidthaya 1994a). This may indicate that the disease usually occurs in debilitated patients. However, there is no such parallel in animals with this disease. Moreover, in the USA and Australia, four subcutaneous human cases of pythiosis were recorded in healthy individuals (Rinaldi et al. 1989; Triscott et al. 1993). Thus, the predisposition to *P. insidiosum* infection in patients with thalassemia hemoglobinopathy syndrome is intriguing and merits further investigation.

LABORATORY DIAGNOSIS

Clinical material from suspected cases of pythiosis should be sent directly to the laboratory for processing. Storage of tissue samples at 4°C during transportation may result in the death of *P. insidiosum*. If the samples cannot be delivered immediately, it is recommended that they should be vigorously washed several times in sterile distilled water, and then transported in sterile distilled water plus antibiotics (ampicillin + streptomycin). The most suitable tissue from which to isolate *P. insidiosum* from horses is the coral-like structures known as kunkers. These masses are removed and repeatedly washed in distilled water. The tissue or kunkers are then cut into small pieces, placed on Sabouraud's dextrose agar (SDA) and incubated at 37°C for 24–48 hours. Parts of the pieces of the kunkers should be placed in 10 percent KOH for direct microscopy examination. Wet mounts are of value for the early detection of *P. insidiosum*, which appear as hyaline sparsely septated hyhae 4.0–9.0 μm in diameter.

Several media have been used for the isolation of *P. insidiosum*. The most common is SDA. *P. insidiosum* grows rapidly at 37°C on that medium. In 24 hours it develops flat colonies that are 20 mm in diameter. Microscopically, however, the hyphae are found to be sterile at this stage. The hyphae are branched at approximately 90° angles and are usually coenocytic, although occasional septa are observed in tissue sections and in old cultures. To induce zoospore production, it is recommended that boiled grass leaves be placed on *P. insidiosum* cultures. After 24 hours of incubation at 37°C, the leaves are immersed in dilute salt solution containing calcium and incubated 2–3 hours at 37°C (Mendoza and Prendas 1988). Zoosporangia containing motile zoospores will be readily observed at the edges of the leaves. Oogonium production is very rare in *P. insidiosum*, so specific identification is based on serological tests and DNA testing (Mendoza et al. 1987; Badenoch et al. 2001; Grooters and Gee 2002; Schurko et al. 2003a).

Histopathology

In tissue sections, the hyphae of *P. insidiosum* in tissue sections are often difficult to differentiate from those found in cases of zygomycosis caused by fungal species of the orders Mucorales and Entomophthorales. In such cases, the diameter of the hyphae may be of help. The hyphae of *P. insidiosum* are between 3.0 and 10.0 μm in diameter, whereas those of *Basidiobolus ranarum* and *Conidiobolus coronatus* are broader, being about 5–15 μm in diameter. However, the isolation of *P. insidiosum* and the use of serological tests are the ultimate basis for the diagnosis of pythiosis. In some cases, clinical data can also be useful. For example, clinically pythiosis and zygomycosis caused by *B. ranarum* occur in the same anatomic areas in horses, so it is often difficult to differentiate between them, although infections caused by *C. coronatus* occur primarily in a horse's nostrils. This clinical difference may be of help, if serological tests and isolation of the etiologic agent are not possible.

DNA-based diagnostic assays

The identification of *P. insidiosum* in the laboratory and histopathological preparations is entirely based on its sexual oogonia and hyphae-like morphological features. However, several fungi have also morphological similarities with the filamentous structures of this oomycete, and the development of oogonia in agar plates is difficult. To overcome these facts, DNA methodologies have recently been used for its diagnosis and identification (Badenoch et al. 2001; Grooters and Gee 2002; Reis et al. 2003). Badenoch et al. (2001) were the first to use DNA sequencing to identify *P. insidiosum* hyphae from a patient with keratitis. These authors suggested that molecular tools could be important in differentiating *P. insidiosum* from the filamentous fungi. Later, Grooters and Gee (2002) developed nested primers that specifically amplified 105 base pairs from *P. insidiosum*'s genomic DNA. More recently, Reis et al. (2003) obtained several amplicons of *P. insidiosum*'s 18S small-subunit rDNA sequences from three cases of horses with systemic pythiosis. These studies indicated that DNA-based technology is ideal to identify *P. insidiosum* from fixed tissues and cultures, and could be successfully used more frequently in the future.

Serology

Serological methods for diagnosing *P. insidiosum* infections were developed in the beginning of the century (Witkamp 1925). Miller and Campbell (1982a) and Mendoza and Alfaro (1986) based their immunological studies of equine pythiosis on Witkamp's early work. They found that immunodiffusion and complement fixation tests were useful in the diagnosis of pythiosis. Moreover, a skin test was shown to be effective in determining subclinical infections in animals with active disease.

IMMUNODIFFUSION TEST

Two antigens have been used to diagnose *P. insidiosum* infections by immunodiffusion. One was prepared from the hyphae of *P. insidiosum* digested with trypsin (Miller and Campbell 1982a). This trypsin antigen detected one precipitinogen in all animals with active pythiosis. However, its shelf life was short. The other antigen was obtained from concentrated CFAs (Mendoza et al. 1986). It detected three to six precipitins in sera from horses and humans with pythiosis. One of them was the precipitinogen reported earlier in an ID test with trypsin antigens. Healthy individuals were always negative with the ID test. Chronic equine cases of pythiosis showed no bands in the ID test. These animals also did not react to skin tests and were considered anergic. The ID test detects pythiosis in its early stages (3 days), indicating that antibodies against the antigens of *P. insidiosum* are developed early in the course of infection.

No crossreactivity was recorded using the CFA of *P. insidiosum* and sera from patients with zygomycosis or other mycotic and bacterial diseases. The ID test was specific for pythiosis. Thus, the presence of a precipitin band in ID is suggestive of this disease. The number of precipitins in ID does not correlate with the severity of the disease. Horses treated and recovered from the disease showed no precipitin bands after 2 months of successful treatment. Some bands of non-identity were recorded when sera from horses with pythiosis reacted to the antigens of *B. ranarum (haptosporus)* or *C. coronatus* (Kaufman et al. 1990). The CFA proved to be

more sensitive, stable and useful, not only in diagnosing the disease in cats, cattle, dogs, horses, and humans, but also in monitoring response to treatment (Mendoza et al. 1986; Imwidthaya and Srimuang 1989; Pracharktam et al. 1991). In addition, complement fixation has been previously used (Miller and Campbell 1982a). However, this test is no longer available.

WESTERN BLOT

Culture-filtrated antigens in the ID test detected at least six precipitinogens. However, ID is too insensitive and also unable to identify major antigenic immunogens. Western blot analysis was introduced to determine which of the antigens of *P. insidiosum* were of importance during infection (Mendoza et al. 1992a). It was found that equine IgG recognized almost all of the cytoplasmic proteins of *P. insidiosum*. Several protein antigens of 28, 30, and 32 kDa) and other immunogens were found to be immunodominant (Figure 14). Negative results in Western blot were recorded using sera from healthy horses or sera from horses with various other diseases. Equine immunoglobulin G against the 32, 30, and 28 kDa and other immunodominant antigens was found to persist at least for a year in horses cured by immunotherapy. This suggests that these prominent antigens may also be important as protective immunogens in horses. It was later found that the addition of cytoplasmic antigens, containing the 28, 30, and 32 kDa immunodominant proteins, to the available *Pythium* vaccine enhanced its curative properties (Mendoza et al. 2003). This finding suggested that these proteins may play a major role in the immunotherapy of pythiosis. In equine chronic pythiosis, Western blot fails to detect the cytoplasmic antigens of *P. insidiosum*, indicating that anti-*P. insidiosum* IgG is absent from their sera. This supports the concept that horses with the chronic disease are anergic. IgG from horses with active pythiosis recognized only the 44 kDa cytoplasmic antigen of *C. coronatus*, confirming that the Western blot test is very specific in horses. This test is useful for analyzing immunoglobulin classes during infection. Recently, a single-step immunoblot (SIB) assay to diagnose pythiosis in horses was shown to be sensitive, specific, and easy to perform (Rosa 1993). Studies using human sera in Western blot are not yet available.

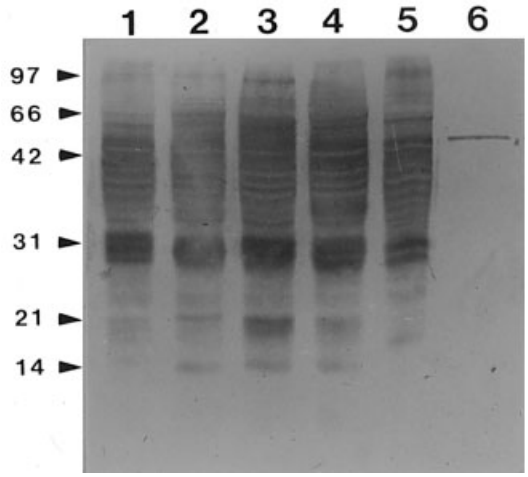

Figure 14 *Immunoblot analysis of the CFAs from different strains of* Pythium insidiosum *(lanes 1–5) and* Conidiobolus coronatus *CFAs (lane 6) after reacting with sera from horses with pythiosis. The 28, 30, and 32 kDa proteins are observed as prominent bands. A band of crossreaction was observed against* C. coronatus*'s CFA (lane 6). (Reproduced, with permission, from Mendoza et al. 1992a)*

ENZYME-LINKED IMMUNOSORBENT ASSAY

The enzyme-linked immunosorbent assay (ELISA) test was originally designed to detect anti-*P. insidiosum* IgG in proved cases of pythiosis with a negative ID (Rosa 1993; Mendoza et al. 1997). More recently, the test was shown to be helpful in cases of a dog and cat with the disease (Mendoza et al. 1997; Grooters et al. 2002). In Thailand, at least another in-house assay was developed using antigens from Thai isolates (Krajaejun et al. 2002). These ELISAs showed high sensitivity and specificity to diagnose pythiosis and were also suitable to monitor the response to treatment, confirming previous observations (Mendoza et al. 1997). In addition, some healthy horses from enzootic regions reacted positively in low titers, suggesting that subclinical infection may occur.

The ELISA developed to detect pythiosis in humans (Krajaejun et al. 2002) and animals (Mendoza et al. 1997; Grooters et al. 2002) both showed 100 percent sensitivity and specificity. These ELISAs were capable of discriminating between sera from apparently healthy individuals or heterologous infections and patients with active pythiosis.

IMMUNOHISTOCHEMICAL ASSAYS

Two tests have been developed for the immunodetection of *P. insidiosum* hyphae in tissue: an immunofluorescence test (Mendoza et al. 1987) and an immunoperoxidase assay (Brown and Roberts 1988; Triscott et al. 1993). The immunofluorescence assay was shown to be entirely specific for *P. insidiosum* in the detection of its hyphae in cat, dog, and human tissues. However, in equine pythiosis, tissue sections of kunkers containing hyphae showed a uniform fluorescence throughout the sections. This was attributed to the exoantigens released by the hyphae of *P. insidiosum* into the matrix of the kunkers. Immunofluorescence has also been used to differentiate *P. insidiosum* from other species of *Pythium*.

The immunoperoxidase assay was performed on the tissue of dogs, horses, and humans with the disease (Brown and Roberts 1988; Triscott et al. 1993; Fischer et al. 1994). *P. insidiosum* in those tissues stained positively after applying anti-IgG peroxidase. Tissue sections

from cases of zygomycosis caused by *B. ranarum* and *C. coronatus* were negative in these assays. Both assays were found to be sensitive and specific.

ANIMAL INOCULATION

All attempts experimentally to reproduce pythiosis in dogs, horses, and mice have failed (Patino-Meza 1988). Early workers, however, found that rabbits were susceptible to infection by the propagules of *P. insidiosum* (Witkamp 1924). Amemiya (1969, 1982), working with strains isolated from horses with granular dermatitis in Japan, confirmed the susceptibility of rabbits to hyphal inoculation. In his work, he found that subcutaneous inoculation of *P. insidiosum* hyphae gave rise to nodules that contained hyphae and inflammatory cells at the injection sites (Figure 15). Intravenous injection caused systemic infections in the inoculated rabbits with granulomatous necrotizing masses in the aortas, intestines, livers, and lungs.

Miller and Campbell (1983) evaluated motile zoospores as inocula in cortisone-treated and non-cortisone-treated rabbits. They found that both groups were extremely susceptible to infection by the zoospores of *P. insidiosum*. All inoculated animals developed necrotizing hepatitis or embolic nephritis, thus demonstrating that *P. insidiosum* does not require a debilitated or immunocompromised host to induce infections. In striking contrast, numerous authors have failed to reproduce the disease in horses and dogs, even after exposing them to motile zoospores by submerging the animals in tanks of seeded water which simulated the conditions encountered in swamps. The predisposing factors required to develop pythiosis in dogs, horses, and humans remain unknown. Mendoza et al. (2003), based on clinical data, however, argued that humans and animals are resistant to pythiosis. They also suggested that perhaps a defect in the immune response is what makes a host susceptible, which in part explains the low occurrence of the infection in the endemic areas.

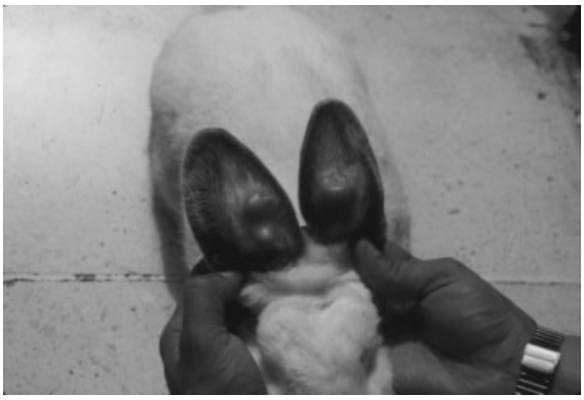

Figure 15 *Experimental pythiosis in a rabbit. Subcutaneous nodules and systemic dissemination of* Pythium insidiosum *are the main features of such experimental infections.*

TREATMENT

Treatment of infections caused by *P. insidiosum* in animals and humans is difficult. Three therapeutic methods are, however, often used for this disease: surgery, drugs, and immunotherapy.

Surgery

Radical surgery has been successfully used in cases of equine pythiosis since the last century. It consists of removal of the lesions and their kunkers, followed, in some cases, by cauterization (Habbinga 1967; McMullan et al. 1977). This method is very popular and frequently used by veterinary practitioners, although it is not always successful. In general, the response to surgery is limited. Moreover, lesions on the limbs of equines are not easily treated by this method because of their delicate anatomic structure. Surgical removal of tumor-like lesions in dogs with intestinal pythiosis has been reported, but survival beyond 3 months was extremely rare in the treated dogs (Fischer et al. 1994; Thomas and Lewis 1998). A common shortcoming of surgical treatment is recurrence as a result of incomplete removal of infected tissue.

Radical surgery has also been used in human cases with arteritis caused by *P. insidiosum*. Amputation of the extremities is a drastic procedure of the last resort, which is used to treat patients with severe *Pythium* arteritis. However, this method has proved to be only partially successful because most patients finally died of disseminated abdominal arteritis (Sathapatayavongs et al. 1989; Wanachiwanawin et al. 1993). Early detection of affected vessels using angiography is important in determining the most appropriate amputation site.

Chemotherapy

Two main groups of drugs are commonly used to treat pythiosis: iodide and amphotericin B. Iodides have been used since early in the century in equine pythiosis with contradictory results. Although some authors reported cures with intravenous injections of potassium iodide (0.75 g/45 kg in weight) (Gonzalez et al. 1979) or sodium iodide (1.0 g/15 kg in weight) (Hutchins and Johnston 1972), other investigators reported failures (de Haan and Hoogkamer 1903; Hartsfield 1971; Murray et al. 1978). Similar observations were recorded in humans. Patients with arteritis caused by *P. insidiosum* did not respond to potassium iodide, but patients with subcutaneous pythiosis seem to have responded well to this drug (Thianprasit 1990). The main drawback of iodide and amphotericin B is their toxicity (Murray et al. 1978).

Amphotericin B is the drug of choice in many mycotic infections. As a result of the lack of ergosterols in the cytoplasmic membrane of members of the genus

Pythium, however, one could predict that amphotericin B would be ineffective in infections caused by *P. insidiosum*. Nevertheless, in equine pythiosis, amphotericin B has been used with some success. Eight cases of equine pythiosis were cured out of a total of 10 horses (McMullan et al. 1977) after intravenous injection of amphotericin B (0.38–1.47 mg/kg). Topical application of this drug had little or no effect on equine cases (Miller et al. 1983). The use of amphotericin B has been limited partly as a result of the cost of therapy, the poor rate of success, and its toxic side effects. Amphotericin B in humans with pythiosis gave contradictory results as well. For example, intravenous injections of amphotericin B (0.1 mg/kg) were ineffective in cases with arteritis (Wanachiwanawin et al. 1993) and in one case of subcutaneous infection (620 mg/kg, over a 6-week period) (Rinaldi et al. 1989). It was effective in two subcutaneous pythiosis cases when it was used in combination with 5-fluorocytosine (amphotericin B 0.5 mg/kg/day, 5-fluorocytosine 150 mg/kg/day) (Triscott et al. 1993). A combination of itraconazole and terbinafine saved the life of a boy in Tennessee with subcutaneous pythiosis (Shenep et al. 1998). However, this combination has been also used in dogs and other animals with contradictory results.

Immunotherapy

Immunization of equines with products derived from *P. insidiosum* cultures was reported to have curative properties in Australia (Miller 1981) and Costa Rica (Mendoza and Alfaro 1986). Two antigens, referred to in the literature as Miller's and Mendoza's vaccines (Newton and Ross 1993), have been used for immunization. The Australian vaccine was prepared from sonicated hyphal antigens, whereas the Costa Rican vaccine used precipitated proteins from CFAs. Immunotherapy of horses with pythiosis using Miller's vaccine alone gave a success rate of 53 percent. An increase in the percentage of cured cases was obtained when immunization was followed by surgical removal of cutaneous lesions. Similar results were obtained using Mendoza's vaccine (Figure 16). Nevertheless, significant reduction in the swelling, caused by the vaccine at the site of injection, an undesirable side effect of Miller's vaccine, was the main feature of Mendoza's vaccine. Moreover, the vaccine described by Miller was unstable, losing its curative properties after storage at 4°C. By contrast, Mendoza's vaccine was found to be effective even 18 months after its preparation.

Recently Mendoza et al. (2003) introduced new immunotherapeutic immunogens to treat pythiosis in both humans and animals. This new formulation contains exo- and endoproteins extracted from cultures of *P. insidiosum* and was able to cure chronic and acute cases of the disease (Thitithanyanont et al. 1998; Hensel et al. 2003; Mendoza et al. 2003). These studies suggest

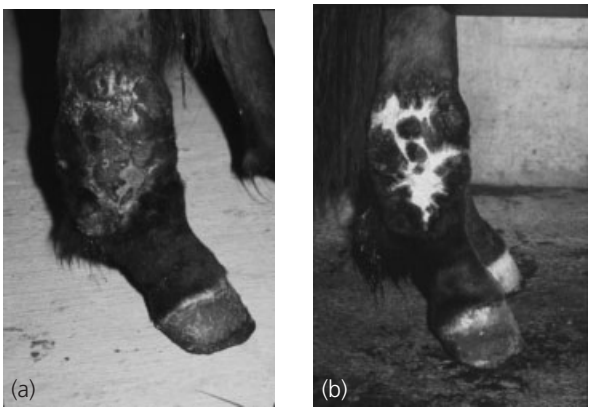

Figure 16 (a) *A horse with pythiosis before immunotherapy;* **(b)** *the same horse after successful immunotherapy. (Reproduced, with permission, from Mendoza and Alfaro 1986)*

that hyphal antigens may contain products that are involved in the enhancement of the immunological response to immunization. Horses with the disease that failed to respond to immunization did not develop swellings at the injection sites. All in all, this finding suggests that the response to immunization is directly related not only to the immunostatus of the infected hosts, but also to the type of immunogens used.

Based on histopathological data, the hyphae of this oomycete are always sequestered within kunkers. Thus, it has been postulated that perhaps some antigens are downregulated during infection (Mendoza et al. 2003). Reports on the histological changes that take place after immunotherapy had shown that the initial eosinophilic inflammatory reaction, typical of equine pythiosis, changed to a mononuclear response composed mainly of macrophages and T lymphocytes (perhaps cytotoxic lymphocytes) (Miller 1983; Mendoza and Alfaro 1986). The antigens, used during immunotherapy, apparently trigger a Th1 immune response with macrophages and cytotoxic lymphocytes that eventually clear the organism from tissues. This contention is supported by the fact that cultures of biopsied tissue in immunized horses are always negative for hyphae. This confirms, in part, the observation that the digestion of the kunkers by the mononuclear inflammatory cells seems to destroy the hyphae of *P. insidiosum* (Miller 1981; Mendoza et al. 1992b). Complications associated with immunotherapy are mainly an inflammatory reaction at the injection site, secondary bacterial contamination, and lameness in lesions located on limbs. It was reported that some horses cured by immunization relapsed one year later. This suggests that, if the vaccine has prophylactic properties, it is of short duration. The prophylactic and curative properties of *P. insidiosum* immunogens have been recently evaluated by Santurio and Leal (2003) in an animal model. These investigators confirmed that the antigens derived from this oomycete have, indeed, curative and prophylactic properties.

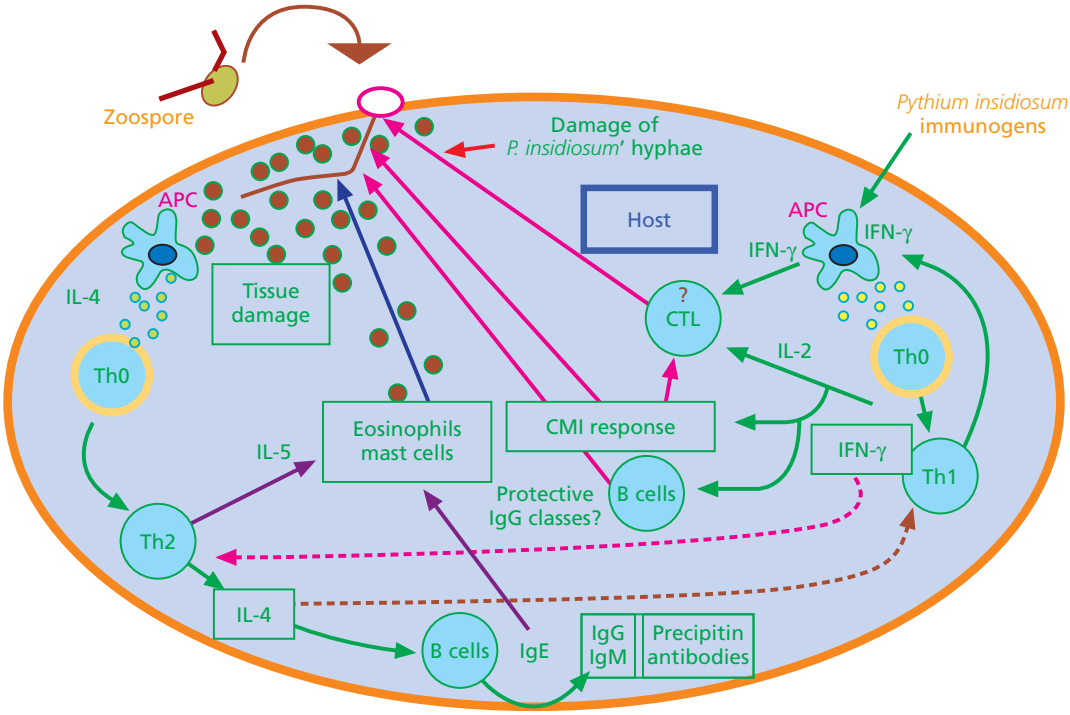

Figure 17 *Proposed working hypothesis of the pathogenic mechanisms involved during natural infection and those triggered by immunotherapy. In this model, pythiosis begins when the host contacted a zoospore (or other propagules of the pathogen) through a wound.* Pythium insidosum *will develop hyphae-like filaments that penetrate the host. Once in the tissues, it will release antigens that will lock the immune system into a Th2 response and which contain typical cellular and other mediators including IL-4 that could downregulate the Th1 response (brown dotted arrow) and cause pythiosi (blue arrow) (left side of the figure). By contrast, after immunotherapy, IFN-γ is immediately triggered, which in turn activate a Th1 immunity and downregulates the Th2 response (pink dotted arrow). The mononuclear response (putative natural killers and cytotoxic lymphocytes, cell-mediated immunity) is believed to be responsible for the killing of the pathogen in the infected tissues (red arrows). APC, antigen presenting cell. (Reproduced, with permission, from Mendoza et al. 2003)*

The mechanism involved in the response of horses to natural infection and to immunotherapy using *P. insidiosum* products has been recently addressed by Mendoza et al. (2003). In their model, *P. insidiosum*, after contact with the host, will release exoantigens that will lock the immune system into a Th2 response (eosinophils, mast cells, IgE, IL-4, IL-5, precipitin, IgG, and IgM). They propose that the degranulation of the eosinophils and mast cells is responsible for the tissue damage observed during natural infection (Figure 17). By contrast, after injection with the immunotherapeutic antigens of *P. insidiosum*, the host will trigger a Th1 response with interferon-gamma (IFN-γ) that eventually downregulates the Th2 response, and a prominent mononuclear response. These investigators speculated that the events triggered by the immunotherapeutic antigens ultimately kill the pathogen in the infected tissues, and therefore are more likely responsible for the cure of the infected hosts (Figure 17).

Evolution and prognosis	3	References	6
Diagnosis	4		

This disease was first described in 1931 by Lobo in Recife, Brazil as blastomycosis queloidiforme, following observations in a 52-year-old Amazonian man who had multinodular keloid-like lesions in the lumbar region. Further cases have been identified in Brazil and other countries in the Amazon region, and Central America. Later sporadic and isolated cases have been described in Europe and North America.

The only case described in Europe (France) was of a 24-year-old aquarium employee who presented with Lobo's disease on the dorsum of his hand 3 months after contact with an infected dolphin (Symmers 1983). A single report from the USA was of a patient who probably contracted the infection in Venezuela (Burns et al. 2000). The total number of registered patients reached 464 by December 2002 (Baruzzi et al. 1979; Silva and Brito 1994; Pradinaud and Talhari 1996; Opromolla et al. 1999; Saint-Blancard et al. 2000; Fischer et al. 2002).

The etiologic agent responsible for Lobo's initial case was classified as *Glenosporella loboi* by Fonseca Filho and Area Leão in 1940. Other names that have been proposed include *Glenosporopsis amazonica*, *Paracoccidioides loboi*, *Blastomyces loboi*, *Loboa loboi*, and *Lacazia loboi*.

Lobomycosis has been described in dolphins: *Tursiops truncatus* (bottle-nosed dolphin) in Florida (Migaki et al. 1971; Symmers 1983) and *Sotalia guianensis* in the Surinam river. The disease identification in dolphins has widened the geographical distribution since seven cases have now been reported in Florida and single cases in the Gulf of Mexico, Surinam, and the Gulf of Gascony, off the coast of France.

The human disease affects the tropical zone of the New World and Table 23.1 illustrates the distribution.

There is a clear gender predilection as 90 percent of cases have been reported in men. This is most likely to be related to occupational exposure. However, in the Amazonian Caiabi Indian population, the prevalence in women reaches 32 percent, probably as a consequence of their role in agricultural and forest activities (Baruzzi et al. 1979).

The age range of patients at the time of diagnosis is between 40 and 70 years. Their case histories, however, suggest that clinical manifestations began many years before. Some cases have also been reported in children: a 5-year-old whose lesions evolved from the age of one; there is also a report of disease in a 2-year-old Caiabi Indian.

ETHNIC BACKGROUND

There is no ethnic predominance as all races appear to be equally susceptible. However, lobomycosis is very well documented in the Mato Grosso (Brazil) Caiabi Indians where it was first recognized in 1915. By 1979, 60 cases had been reported in this particular tribe, representing 31 percent of all Brazilian cases (Baruzzi et al. 1979). It has therefore been suggested that this tribe might be genetically predisposed. However, the fact that no new cases have been identified after movement of these tribes to a new habitat in Xingu National

Park points to an environmental or exposure-related etiology.

OCCUPATIONAL EXPOSURE AND INOCULATION

Farmers exposed to harsh conditions and aquatic environments represent most of the reported cases. Other high-risk activities include gold mining, fishing, and hunting.

Patients often report a bite or sting from an arthropod, snake or sting-ray, or otherwise trauma from a cutting instrument. Probably, the fungus is an aquatic saprophyte, which would explain disease in aquatic mammals such as the dolphin. There are no reports of person-to-person spread, even with intimate contact. However, there are reports of voluntary inoculation (Borelli 1968) and accidental surgical inoculation of a patient (Azulay et al. 1975).

CLINICAL FEATURES

Lobomycosis is characterized by variably sized dermal nodules, either lenticular or in plaques, which can attain the size of a small keloid-like cauliflower. They can be either hyper- or hypopigmented, and occasionally achromic. A number of different types of lesions may be seen at various stages of disease progression (Figures 1 and 2). Infiltrative lesions are often a feature of early disease and can simulate tuberculoid leprosy or burn scars, especially in the Caiabi Indian population (Figure 3). Verruciform lesions represent advancing pathology and occur most commonly on the lower extremities and, like other exotic mycoses, can give the 'mousy-foot' appearance. Ulcerative lesions may also represent advanced pathology and on healing result in sclerotic or atrophic scars. Most of the ulcerated lesions are caused by trauma. A few cases of dermohypodermic lesions could be referred to as having a gumma-like appearance, but the characteristic softening is absent and therefore these lesions are more typical of nodules. True gummatous lesions are rarely observed. Patients, however, usually present with lesions of various types.

Figure 1 *Isolated and confluent keloid-like lesions*

The disease generally does not affect the epidermis and therefore skin lesions usually have a smooth and shiny appearance, especially in the facial region. Fine telangiectasia and sometimes 'black dots,' a feature of chromoblastomycosis and other vegetating dermatoses, can be observed, the 'black dots' corresponding to transepidemic elimination of necrotic fungi. Some lesions, especially on the lower extremities, can be keratotic and vegetating. An extreme case was that of a patient whose skin resembled a rock covered with seashells. On the sole of his foot, lesions appeared crater-like.

Any area of the body is potentially susceptible as infection commonly follows trauma. However, the most commonly affected areas include the lower extremities (31 percent), the ears (26 percent), and the upper extremities (20 percent), and the disease is usually unilateral (Figures 4 and 5).

Figure 2 *Isolated and confluent papules and nodules*

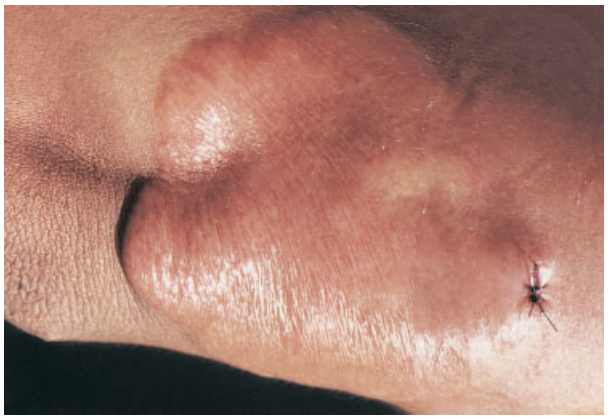

Figure 3 *Infiltrative plaque*

Disease varies in extent and local or distant spread of lesions can occur. Local spread probably occurs in part by autoinoculation, producing small satellite nodules at the periphery of the mother lesion. The disease can invade lymph nodes proximal to the affected area but reports, however, vary as to how commonly this occurs, ranging from less than 10 percent (Azulay et al. 1975) to more than 25 percent (Wiersema 1971). Distant skin metastases occur via transdermal and lymphohematological routes. Cutaneous dissemination can result in confluent lesions and plaques (Figures 6 and 7), with some patients developing hundreds of lesions. There has been a single report of visceral pathology in a native Costa Rican whose lesions evolved over a period of 47 years. He presented with left lower extremity lymphangitis secondary to left testicular tumoral spread, which necessitated orchidectomy. Histology revealed a multicellular granuloma actively phagocytosing the cells of the fungal pathogen and sparing the scrotum.

Figure 4 *Classic infiltrative nodules of the auricle, on one side only, which are indolent and have evolved over many years.*

Figure 5 *Infiltrative lesions of a woman's face. This is a very unusual location of the disease. (Courtesy of Arival C. Brito, Belém*

The clinical presentation in dolphins is similar to that in humans. They also develop keloidal nodules, either confluent or in plaques, as well as verrucous and vegetating lesions.

EVOLUTION AND PROGNOSIS

Disease onset is usually insidious and therefore difficult to document. The increase in either size or number of lesions is a slow and progressive process, which can continue for up to 40–60 years. The presenting complaint is usually esthetic or functional disability. The disease progresses in a benign fashion and patients usually die of intercurrent illnesses. At present, however, it appears incurable as new lesions usually continue to appear despite treatment either in proximity to, or distant from, the initial lesion. Interestingly, spontaneous regression in three Caiabi Indians has been reported.

Figure 6 *Numerous papular and tumor lesions on the arm and forearm.*

Figure 7 *Numerous papules, plaques and tumoral lesions on the foot, leg and thigh.*

DIAGNOSIS

The clinical diagnosis is apparent to physicians who have seen previous cases of lobomycosis and the patient is known to reside in an endemic area. The differential diagnosis includes mainly leprosy, anergic cutaneous leishmaniasis, chromoblastomycosis, paracoccidioidomycosis, and Kaposi's sarcoma.

Diagnosis may also be established by a skin smear or biopsy.

Skin smear

A skin smear permits direct visualization of the parasite, which is abundant in lesions. It is quick and easy and entails scraping a tumoral lesion with a scalpel blade in order to obtain dermal tissue for microscopy. Lobomyces are yeast-like rounded thick-walled cells which range from 5 to 15 μm in diameter and occur in chains of two to ten cells (Figure 8). Granules (five to eight) are present in the center and there is usually one that is larger than the others. They appear mobile due to Brownian motion, especially in a fresh specimen.

In old lesions, one can observe the presence of a single large inert granule. The cells are united by little cell bridges. In most cases, each cell's cytoplasm is clearly demarcated, although, at the end of the chain, one can occasionally see a budding cell, with continuous cytoplasm between the mother and daughter cell.

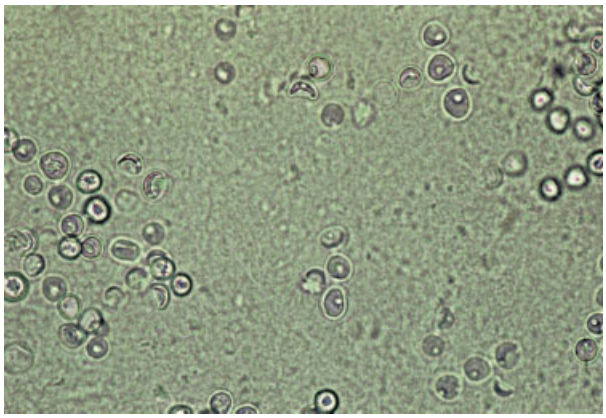

Figure 8 *Numerous cells of* P. loboi *in a smear of dermal scrapings: the diagnosis can be confirmed in the office within a few seconds. Multiple buds and chains are connected by tubes; five to eight mobile protoplasmic granules are seen in active fungus.*

Histopathology

Histopathology is pathognomonic. The epidermis is usually atrophic, although it can also be hyperplastic, vegetating, and keratotic. Lesions in dolphins are identical to those in human skin (Destombes and Ravisse 1964; Symmers 1978; Arrese et al. 1988; Sesso and Baruzzi 1988; Sesso et al. 1988).

In the dermis a thin band of subepithelial collagen, analogous to lepromatous leprosy's 'Unna band' is usually intact. The remainder of the dermis is occupied by a progressively fibrous, diffuse, inflammatory granuloma. The granuloma is composed of histiocytes and numerous giant cells, which are often clustered in small groups separated by interstitial tissue. The histiocytes, and more often the multinucleated giant cells, can be seen to have numerous phagocytosed thick-walled cells clearly distinguishable by periodic acid-Schiff (PAS), or Gomori's/Grocott's, or Gridley's silver stains (Figures 9 and 10). Although the cells can sometimes appear empty, they often contain vacuolized inclusions that are birefringent in polarized light. Budding can be observed but hyphae are always absent. These yeast-like cells, which abound in the cytoplasm of giant cells, occasionally appear free floating in the stroma of the granuloma. It is important to note that necrosis and suppuration are never present in the granuloma (unless there is nearby epidermal damage). Histochemical stains reveal polysaccharides in the inflammatory granuloma,

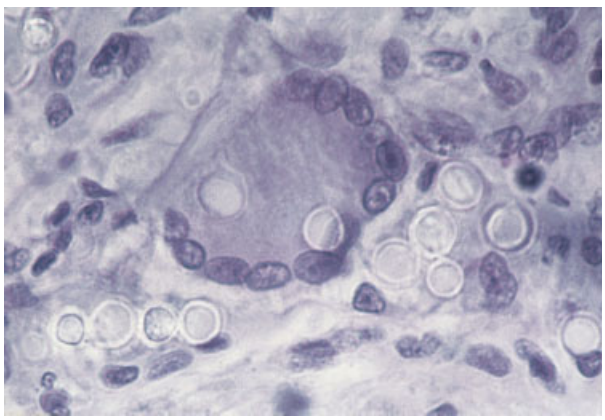

Figure 9 *Pathology: foreign body giant cell and polymorphous infiltrate with histiocytes. Parasites are abundant throughout the whole granuloma. Hematoxylin and eosin stained section.*

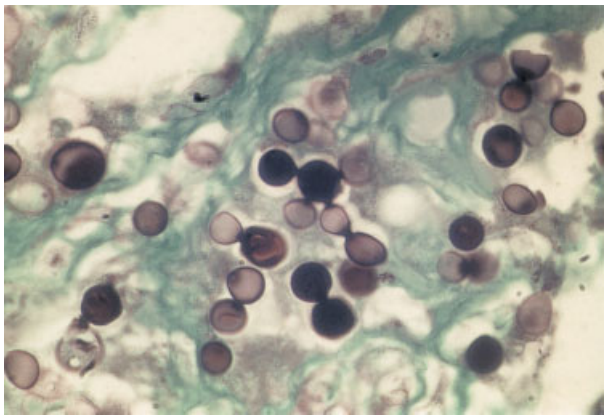

Figure 10 *Gomori's–Grocott's stain on the same histological section as seen in Figure 9. (Courtesy of A.R. Gradelha)*

which are absent in the deeper areas, especially in the hypodermis. The latter is usually intact.

Disease spread to the lymph nodes produces a similar inflammatory infiltrate with histiocytes and multinucleated giant cells. The cytoplasm of these cells is often xathomatized and contains the same abundance of yeast cells as in the dermis.

Electron microscopic studies demonstrate small spines 1 μm in size on the external glycoprotein membrane which itself measures approximately 0.8 μm. The fungus is multinucleated and central vacuolized inclusion bodies have been identified as triglyceride and polysaccharide glycogenic particles (Furtado et al. 1967; Grimaud et al. 1974).

Culture

There have been many attempts to culture *L. loboi*, but all have been unsuccessful. Sampaio (1974) obtained encouraging results by spreading the cells of *L. loboi* in a 199 TC, containing 5 percent bovine fetal serum penicillin 100 units/ml, amphotericin B μg/2.5 ml, and 2.5 percent phytohemagglutinin at 37°C. The inoculum, which had been taken from the lesion of a patient, was preserved for 5 months in 4°C distilled water.

Animal inoculation has been used with varying success. Armadillo (*Euphractus sexcintus*) inoculation has been more successful and resulted in nodular lesions histologically identical to human pathology (Sampaio and Dias 1977). L. Ajello (unpublished data) has also successfully inoculated the footpads of mice at the Centers for Disease Control and Prevention (CDC) in Atlanta, GA.

IMMUNOLOGY

Patients with Lobo's disease have normal humoral immunity but a partial cellular immune deficiency reflected in absent delayed hypersensitivity responses to dinitrochlorobenzene, streptococcus, staphylococcus, trichophyton and candida antigens (Pecher and Fuchs 1988). In addition, some form of secondary immunodeficiency has been suggested in a dolphin with lobomycosis but to date, lobomycosis in conjunction with human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome (AIDS) has not been reported in humans.

Antigens modified for intradermal use can be used to evaluate the potential of asymptomatic infection due to *L. loboi*. However, these have also given positive results with paracoccidioidomycosis, mycetomas caused by *Nocardia brasiliensis* and in a single case of eczema. This may be due to antigenic relationships between *L. loboi* and other mycological agents which have been demonstrated for *Histoplasma capsulatum* var. *capsultatum* and var. *duboisii*, *Blastomyces dermatitidis*, *Candida albicans*, and the mycelial form of *Coccidioides immitis* (Silva 1978).

When Jorge Lobo described the first case of lobomycosis in 1931, he suggested that the etiologic agent is a fungus similar to *Paracoccidioides brasiliensis*. Taborda et al. (1999) have shown that it is indeed close to *P. brasiliensis* and have designated it *Lacazia loboi*. They suggest that *L. Loboi* is a sister taxon of *P. brasiliensis* as demonstrated on the 18S rDNA phylogenetic tree. However, paracoccidioidin skin tests are negative in cases of lobomycosis.

TREATMENT

The optimal treatment for localized lesions is wide surgical excision ensuring that margins are free of infection to avoid recurrence. It is worth noting that instruments contaminated during an operation can lead to reinfection. Furthermore, in black patients surgical excision carries the risk of inducing true keloids.

The only treatment of choice for disseminated infections is chemotherapy. Clofazamine at doses of 100 and 200 mg daily has been tried in several studies (Silva 1978; Azulay 1995, personal communication; Talhari et al. 1988) as it has shown efficacy with a variety of fungi and actinomycetes (especially the *Nocardia* spp.) and has anti-inflammatory properties in processes involving foreign body granulomas. Of the 16 treated cases in the various studies, four demonstrated 30–80 percent improvement following 2–8 months of therapy. However, compliance to drug therapy, especially when required for prolonged periods, is low as the disease appears to be well-tolerated by patients. However, Niemel (1990, personal communication) reported lack of clinical efficacy of clofazamine in a patient on long-term therapy for *Mycobacterium leprae* who had coincidental *L. loboi* infection. Ketoconazole therapy for lobomycosis has proved to be disappointing.

Of interest is that a dolphin with lobomycosis has been successfully treated with miconazole (Dudok Van Heel 1977). There has been a recent report of successful

treatment of a localized plaque lesion on the face with a combination of both clofazamine 100 mg and itraconazole 100 mg daily for a one year period (Fischer et al. 2002). The patient remained disease-free both clinically and histopathogically after a follow-up period of 4 years. Therefore, dual therapy with clofazamine and itraconazole may be a promising treatment for plaque lesions only.

ACKNOWLEDGMENTS

To Mahreen Ameen, Carolina Chrusciak Talhari, and Gottfried Schmer for their help in the preparation of this manuscript.

THE ETIOLOGIC AGENT

'There is a certain air of romance attached to the name ''Rhinosporidium''' (Thomas et al. 1956), arising from many synonyms given to its picturesque developmental stages and from its enigmatic nature.

Rhinosporidiosis, the disease that *Rhinosporidium seeberi* causes in humans and animals, presents, as the name implies, with chronic, granulomatous polyps, predominantly in nasal and other respiratory sites. It was first observed by Malbran in Buenos Aires in 1892. Seeber's thesis (1900) first reported the disease, in Argentina. Comprehensive descriptions of the organism (Minchin and Fantham 1905; Beattie 1906; Tirumurti 1914; Ashworth 1923; Karunaratne 1964) and clinical aspects of rhinosporidiosis have been made (Allen and Dave 1936; Karunaratne 1964). While important advances have been made since this chapter was first written in 1998, unresolved enigmas yet remain. Since the organism has yet to be cultured in vitro, the classical Koch's postulates are as yet unfulfilled. Recently, however, using molecular tools, Herr et al. (1999b) found that *R. seeberi* was not a fungus but an unusual protist that shared phylogenetic features with microbes that cause infections in fish.

NOMENCLATURE

The diverse names and descriptions of *R. seeberi* on which tentative classifications were based, were chronologically reviewed by Ashworth (1923) and de Mello (1954) (Table 1). The nomenclature of the developmental stages and their contents is given in the section on Light microscopical and ultrastructural features below.

TAXONOMY

The taxonomy of *R. seeberi* (Ashworth 1923; de Mello 1954; Karunaratne 1964) had been, until recently, controversial. Confusion had arisen undoubtedly from the absence of pure isolates of the organism due to its intractability to culture. *R. seeberi* was initially classified as a sporozoon, then as a phycomycete, and when the doubts deepened, it was placed in an orphanage of anomalous fungal and fungal-like organisms, and even as a cyanobacterium. With the advent of phylogenetic analyses, its dignity was restored, by grouping it with *Dermocystidium*, the rosette agent, *Ichthyophonus*, and *Psorospermium* in a new Class – the Mesomycetozoea, formerly Ichthyosporea (Mendoza et al. 2002), a name which signifies the location of this group at the point when the animals and fungi diverged some 2.5 billion years ago.

Table 1 *Nomenclatural history of* R. seeberi *(Wernicke 1903) Seeber 1912*

Year	Event
1892	Malbran observed the organism in a nasal polyp, and regarded it as a sporozoon, but did not publish his findings
1900	Seeber's (1900) thesis described the organism (cysts, spores containing 'sporozoites') in a nasal polyp; he regarded it as a sporozoon allied to the Polysporea of the Coccidia, but did not name the organism
1900	Wernicke (see de Mello 1954) named the organism *Rhinosporidium seeberi*
1903	O'Kinealy (1903) described a nasal polyp and Vaughan described its histology (cyst with a pore, filled with sporules)
1903	Belou (see Ashworth 1923; de Mello 1954) described the organism under the name *Coccidium seeberia* Wernicke 1900
1904	Minchin and Fantham (1905) studied O'Kinealy's (1903) rhinosporidial tissue and named the organism *Rhinosporidium kinealyi*
1912	Seeber (see Ashworth 1923; de Mello 1954) endorsd the generic name *Rhinosporidium* of Minchin and Fantham, and the specific name *seeberi* of Wernicke, and established the identity of *R. kinealyi* with *R. seeberi*
1913	Zschokke (1913) recorded a similar organism in a nasal growth in a horse; he named it *Rhinosporidium equi*
1923	Ashworth (1923) renamed the species *R. seeberi* instead of Belou's *R. seeberia* and considered *R. kinealyi* as identical with *Coccidium seeberia*. He finally validated the designation '*Rhinosporidium seeberi* (Wernicke 1903), emend. Ashworth,' which is now the valid name of the organism. Ashworth also concluded that 'all examples of *Rhinosporidium* recorded from man appear to be referable to one species'
1936	Ciferri et al. (1936) established the identity of *R. seeberi* and *R. equi*, a view endorsed by Ashworth (1923)
1940	Carini (1940) described cysts with spores in skin nodules in frogs (*Hyla rubra*) and created a new genus *Dermosporidium* for the organism which he regarded as having close affinities with, but different from, *R. seeberi*. The relationship of *R. seeberi* to Carini's *Dermosporidium* remained obscure until 1999 (see Herr et al. 1999a)
1958	Vanbreuseghem (1958) included two synonyms: *Rhinosporidium ayyari* (see Allen and Dave 1936) and *Rhinosporidium amazonicum* Aben-Athar 1944
1999	The new classification of *Rhinosporidium seeberi* and its affinities were proposed by Herr et al. (1999b)

Previous attempts to classify *R. seeberi* (see Ashworth 1923) are of interest in the larger context of taxonomy, especially in the use of morphology as a criterion for its taxonomic classification. For instance:

- Minchin and Fantham 1905 – affinities with Neosporidia and on the structure of its simpler 'spore', with the Haplosporidia
- Beattie 1906 – Neosporidia, allied to the Sarcosporidia based on its striated capsule, a framework separating the 'spores', and polar development of the 'spores'
- Ridewood and Fantham 1907 – Order Haplosporidia, Sub-order Polysporulea, based on the numerous 'spores'
- Laveran and Pettit 1910 noted the resemblance of the trout pathogen *Ichthyosporidium*, regarded as a haplosporidian, to *Rhinosporidium*. The organism described by Laveran and Pettit was regarded as a phycomycete, allied to the Chytridineae, by Plehn and Mulsow (1911). The affinity of *R. seeberi* to the Chytridineae was in doubt, because the Chytridineae have flagellated stages
- Ashworth (1923) related *R. seeberi* to the phycomycetes 'as the thallus is formed of a single cell,' and to the Chytridineae on account of the absence of a mycelium and because 'sexual organs are not generally formed so that the spores are usually asexual;' the absence of such flagellation in *R. seeberi* was noted, while from the spores of most Chytridineae, a flagellated stage emerges. He further placed it provisionally in the sub-order Olpidiaceae in which the trophic stage is spherical or elliptical and because 'each such cell becomes transformed into one sporangium only' as in *R. seeberi*
- Vanbreuseghem (1973) failed to identify *R. seeberi* as an alga
- Herr et al. (1999b), through phylogenetic analysis of the organism's 18S SSU rDNA, classified *R. seeberi* in a new clade which they named the Mesomycetozoea. This new group includes fish and amphibian pathogens in the former DRIP clade (*Dermocystidium*, the rosette agent, *Ichthyophonus*, and *Psorospermium*). Cavalier-Smith (1998 quoted by Mendoza et al. 2001a) included the mesomycetozoeans in a class Ichthyosporae but based on the

fact that 'not all members of this group are fish pathogens and that preliminary analysis showed that *R. seeberi* may have chitin synthase genes, render this epithet inappropriate,' Mendoza et al. (2002) amended the term to Mesomycetozoea. The finding of Herr et al. (1999b) on the phylogenetic placement of *R. seeberi* was recently confirmed by Fredricks et al. (2000).

The current classification of *R. seeberi* according to Mendoza et al. (2001a), modifying the proposal of Cavalier-Smith (1998), is as follows (Figure 1):

Kingdom – Protozoa
Sub-kingdom – Neozoa
Infra-kingdom – Neomonada
Phylum – Neomonada
Sub-phylum – Mesomycetozoa (formerly Ichthyosporea)
Class – Mesomycetozoea
Order – Dermocystida
Family – Rhinosporideaceae (Mendoza et al. 2002)
Dermocystidium spp.
Rhinosporidium seeberi
Rosette agent
Order – Ichthyophonida
Family – Ichthyophonae (Mendoza et al. 2002)
Ichthyophonus
Psorospermium

The taxonomy of *R. seeberi* has finally been resolved (Herr et al. 1999b; Fredricks et al. 2000). These phylogenetic analyses showed that *R. seeberi* is not a fungus but a unique protist that shares morphological and phylogenetic features with several previously orphaned aquatic microbes, located at the divergence between animals and fungi. More information about the mesomycetozoeans could be found in a recent review of this class by Mendoza et al. (2002). In that review, two Orders were recognized – Dermocystida (to which

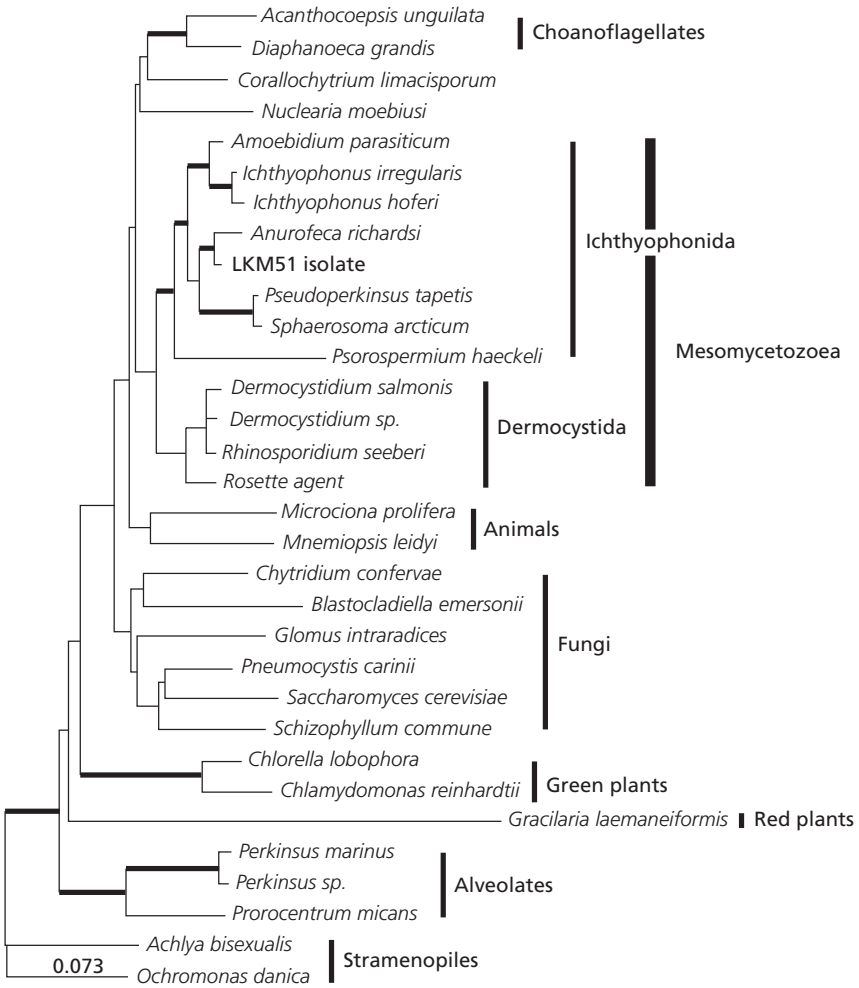

Figure 1 *Phylogenetic analysis of* R. seeberi *and other microbes using the 18S SSU rDNA molecule and distances estimated by maximum likelihood. The thickened branches are supported 90 percent of 1000 bootstrapped. The scale for percentage nucleotide substitution is given on the branch to* Ochromonas danica. *In the phylogenetic tree,* R. seeberi *is the sister clade to* Dermocystidium *spp. and closely related to the Rosette Agent in the Order* Dermocystida *(Mendoza et al. 2002).*

R. seeberi belongs) and the Ichthyophonida, with the commonality of several features that *R. seeberi* shares with the other mesomycetozoeans.

BIOLOGY

The absence of a method for the in vitro propagation of *R. seeberi* undoubtedly accounts for the paucity of data on the biology of *R. seeberi*. Vanbreuseghem (1973) commented that African rhinosporidial endospores are smaller than Indian ones, although the organism 'looks similar in sections of very different origins.' We have no evidence (Arseculeratne et al. 2001) that endospores from rhinosporidial tissues from different patients in Sri Lanka show differences in size.

Karunaratne (1964) postulated, from epidemiologic data, that a saprobic form might exist in soil or water; Gori and Scasso (1994) referred to a yeast form in tissues. There is no evidence for an alternate life cycle in any intermediate host.

Random amplified polymorphic DNA (RAPD) analysis of DNA from six strains of *R. seeberi* from patients with differing clinical presentations showed a heterogeneity in strains of *R. seeberi*, with the six strains falling into three distinct groups on banding patterns (Appuhamy et al. 2002); there was, however, no correlation of the patterns with the clinical picture of the disease. Variations, especially in virulence properties, if they exist, might be relevant to the wide spectrum of clinical features, as well as to the variations seen in histopathology of rhinosporidial granulomata (see Arseculeratne et al. 2001).

Ecology

It is generally held, from cogent epidemiological evidence, that the main natural habitat of *R. seeberi* is ground water in ponds and lakes, or in soil that is contaminated with such water. This evidence includes:

- a history given by the majority of Asian patients of exposure to these sources
- the predominant occurrence of lesions in nasal and ocular sites
- the reports of Noronha (1933) and of Mandlik (1937) that rhinosporidiosis of the nose was closely associated with the occupation of sand-gathering from river beds
- the outbreaks of rhinosporidiosis in humans who had bathed in the same lake (Vukovic et al. 1995), and in swans inhabiting the same lake (Kennedy et al. 1995)
- the higher prevalence in human males, through occupational exposure to soils and soil dust
- a history of trauma from grass or wood splinters (Karunaratne 1964) sometimes related to agricultural occupations
- the occurrence of rhinosporidiosis in animals with an aquatic habitat, such as river dolphin, geese, swans and ducks
- the frequency of anterior urethral rhinosporidiosis in Muslim males (Ingram 1910; Dhayagude 1941; Gahukamble et al. 1982), which was attributed to infection conveyed by pieces of stone or brick, probably contaminated by soil-borne *R. seeberi*, applied to absorb the last drops of urine.

Many reports on microscopic examination of deposits of stagnant water, silt, manure, and water plants in endemic areas have not yielded confirmation of the hypothesis of the aquatic habitat of *R. seeberi*. Histological studies on samples from aquatic animals such as fish, snails, crabs, and frogs have also yielded negative results. Amphibia exposed to natural waters did not develop rhinosporidiosis (Reddy and Lakshminarayana 1962); deposits from ground waters in which rhinosporidial patients had bathed failed to induce rhinosporidiosis after subcutaneous injection in the following amphibia – *Kaloula taprobanica*, *Tamanella obscura*, *Bufo melanostictus*, *Polypidatus cruciger*, *Rana temporaria* (Arseculeratne 1999, unpublished data).

Deposits of water from a reservoir in Sri Lanka in which many rhinosporidial paients had bathed, however, showed bodies on periodic acid–Schiff (PAS)-stained smears, that were compatible in size and shape with rhinosporidial endospores, with the presence within these bodies of structures that were also compatible with the electron-dense bodies (EDBs), Figure 2). Indirect immunofluorescence tests, however, with anti-rhinosporidial antibody, gave extensive nonspecific labeling of amorphous, possibly mineral deposits in the water, which made identification of specifically-labeled rhinosporidial bodies difficult. Polymerase chain reaction (PCR) studies on these deposits are in progress in our laboratory.

It should be added that microscopic methods which rely on the morphology of *R. seeberi* as observed in histopathological sections have assumed that the morphology of the tissue stages is similar to that of the saprobic pathogen. There is no evidence, on the other hand, that *R. seeberi* is a dimorphic organism, as some classical fungi are.

Cultural methods applied to material from aquatic habitats have also uniformly proved to have been unsuccessful, undoubtedly due to the uncultivability of the pathogen in vitro.

A reservoir of *R. seeberi* in animals such as horses and cattle, from which transmission to humans is thought to occur, has been postulated (Weller and Riker 1930; Rao 1938), although it is probable that soil or ground water is the common source of infection for these animals, and for humans who work with them.

Reports that the 'causative organism of rhinosporidiosis, viz. *Microcystis aeruginosa*' was isolated from

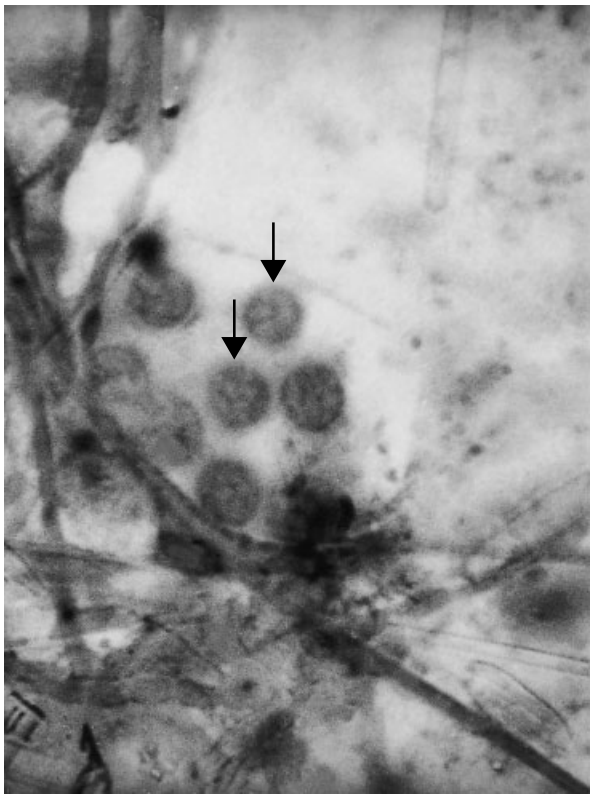

Figure 2 *Smear of deposit from reservoir water in which rhinosporidial patients had bathed, showing spherical PAS-positive bodies (arrows) with intracellular structures, compatible in size and shape with rhinosporidial endospores. PAS; initial magnification ×1 000.*

aquatic environments were recently published (Ahluwalia et al. 1997; Ahluwalia 1999). These investigators erroneously concluded that the causative agent of rhinosporidiosis was the aquatic cyanobacterium *Microcystis aeruginosa*, ubiquitously found in stagnant ground waters. *M. aeruginosa* proved to be an effective red-herring on account of:

- its presence in the same type of waters which are the putative habitat of *R. seeberi*
- its presence as 'round bodies', a feature shared with *R. seeberi*
- its isolation from rhinosporidial polyps. It needs to be pointed out that the surface of rhinosporidial polyps, especially in nasal sites, is rough, a feature which allows the retention of contaminant aquatic micro-organisms. Moreover, the sporangia of *R. seeberi* are often invaded by host-cell infiltrates which include phagocytes; these phagocytes could contain *Microcystis* which could be visualized microscopically and be isolated in culture from rhinosporidial polyps
- no genetic or immunological homologies between *Microcystis* and *R. seeberi* were reported by Ahluwalia. Refutations of Ahluwalia's views were made by Arseculeratne (2000b) and by Mendoza et al. (2001b) on the basis of
  - non-contamination of the organisms's DNA with human DNA
  - absence of control samples from normal people inhabiting the same areas from where the author's water samples were collected
  - absence of cultures of endospores and sporangia free of bacteria after multiple washes and filtration
  - improper sampling of rhinosporidial tissue
  - ultrastructural studies including the morphology of rhinosporidial mitochondria
  - inability of *M. aeruginosa* to cause rhinosporidiosis in experimental animals
  - the absence of reactivity of this cyanobacterium with human and experimental anti-*R. seeberi* antibody in immunofluorescence tests
  - absence of reactions with anti-rhinosporidial sera in immunoblots against *M. aeruginosa* extracts
  - the absence of amplification in PCR tests with primers based on the sequence data published by Herr et al. (1999b). A previous report on the culture of a mycelial fungus as the cause of rhinosporidiosis (Krishnamoorthy et al. 1989) had similar flaws.

Light microscopical and ultrastructural features

In parallel with its disputed taxonomy for many decades, a variety of inconsistent and overlapping terms has been applied to the morphological structures of the organism in its developmental stages (Table 2). Kennedy et al. (1995) proposed a new terminology for the standardization of the ontogenic nomenclature of the *R. seeberi*; these terms are used in this chapter. It is to be noted that these terms represent stages in a continuum of development of the organism; some of these terms, such as electron-dense body, should be regarded as tentative until more definitive studies, as suggested in the following discussion, are available.

Consensual descriptions of the light-microscopical and ultrastructural features of the different ontogenic stages of *R. seeberi*, as they appear in rhinosporidial tissues of humans and animals, have been made by many authors; rhinosporidial endospores and sporangia in various stages of development are uniformly found in histopathological material from diseased humans (Figure 3) and animals.

The 'life cycle' of *R. seeberi*, as deduced from histopathological appearances (Tirumurti 1914; Ashworth 1923; Kutty and Teh 1974; Savino and Margo 1983; Thianprasit and Thagernpol 1989; Kennedy et al. 1995), is represented in Figure 4. All developmental stages of *R. seeberi* are readily identified in most hematoxylin and eosin (H&E)-stained histopathological sections, irrespective of the location of the rhinosporidiosis and the species of the host.

Table 2 *New terminology of the ontogenic stages of* R. seeberi[a]

Earlier terminology	New terminology
Developmental stages	
Spore, immature spore, endospore, sporoblast, early trophic stage, spherule, conidium, sporule	Immature endospore
Mature spore, sporont, pansporoblast, merozoite, yeast phase in tissue, spore morula	Mature endospore
Trophocyte (early, intermediate, late), trophic stage, trophozoite, precleavage phase, immature sporangium, granular stage, sporocyst, cyst, spherule, sporangium	Juvenile sporangium
Endosporulating stage, sporulation phase, trophic sporangium	Intermediate sporangium
Mature trophocyte, mature cyst, endosporulating stage, post-cleavage phase, post-cleavage sporangium, adult stage	Mature sporangium
Intracytoplasmic structures in juvenile sporangium	
Lipid droplets	Lipid bodies
Multilamellar bodies	Laminated bodies
Intracytoplasmic structures in mature endospore	
Lipid bodies, cytoplasmic vacuoles	Lipid globules
Spherules, electron-dense circular structures, protrusions of cell wall, electron-dense inclusions, germinative bodies, sporozoites, spores, sporules, spherical bodies, spore morulae	Electron-dense bodies

a) Adapted from Kennedy et al. 1995.

THE LAMINATED (MULTILAMELLAR) BODY

Several authors have described these bodies as consisting of concentric rings of electron-dense material around a core of chromatin, and seen in juvenile and intermediate sporangia in human and animal rhinosporidial tissues (Kutty and Teh 1974; Savino and Margo 1983; Thianprasit and Thagernpol 1989; Kennedy et al. 1995). Thianprasit and Thagernpol (1989) regarded the laminated body (LB) as the precursors of the endospores. Apple (1983) found these bodies in mature endospores and suggested that, after discharge from the sporangia, the endospores released the LB and from these arose the juvenile sporangia in continuation of the life cycle of *R. seeberi* (see also Kennedy et al. 1995). Kutty and Gomez (1971) described the LB as being 1–1.5 μm in size, derived from the EDBs, and liberated from the endospores; they concluded that the LB is the earliest infective stage, giving rise to the juvenile sporangium. Further work is necessary to elucidate the ontogenic significance of the LBs.

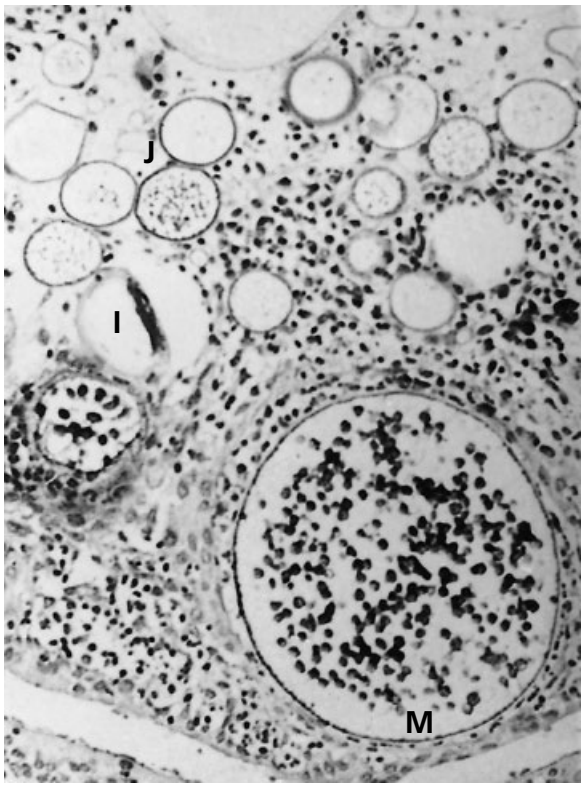

Figure 3 *Developmental stages of* R. seeberi *in rhinosporidial tissue. M, mature sporangium, with surrounding cell infiltrate; I, intermediate sporangium; J, juvenile sporangium. H&E; initial magnification ×400*

ENDOSPORES

The endospores are produced by endosporulation in the sporangia, and are thought to be the asexual propagules of *R. seeberi*; there is no evidence of a sexual stage in the life cycle of *R. seeberi*. After nuclear divisions in the juvenile sporangia, endospores are formed by the condensation of the cytoplasm around the nuclei with the formation of cell walls; 'surfaces of contact remain distinguishable as a sort of network between the spores' (Ashworth 1923). The development of endospores from a germinal part of the inner sporangial wall was postulated by Minchin and Fantham (1905) (see also Beattie 1906; Savino and Margo 1983). Ashworth (1923) and Moses et al. (1991) noted the attachment of endospores to the inner aspect of the sporangial wall; Figure 5 illustrates the immature endospores and their probable origin from this site. Mature endospores were reported to be in the center of the sporangium (Ashworth 1923;

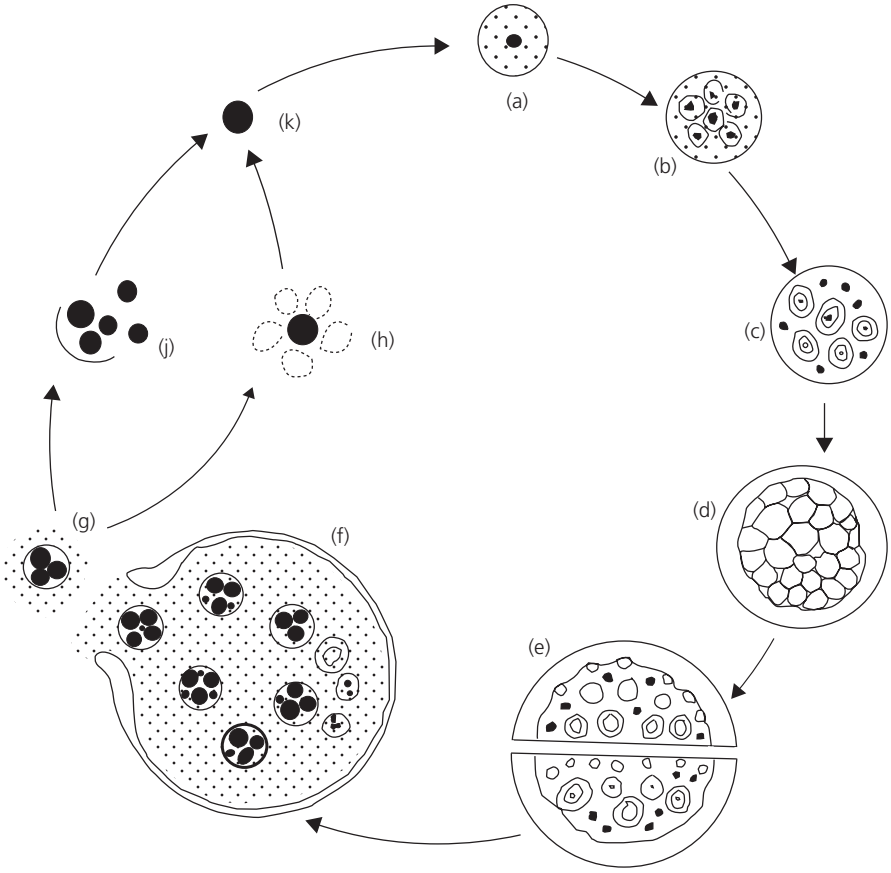

Figure 4 *Diagram (not to scale) of the life cycle of* Rhinosporidium seeberi. **(a)** *Juvenile sporangium;* **(b)** *juvenile sporangium with vesicles containing chromatin;* **(c)** *juvenile sporangium with laminated bodies;* **(d)** *endosporulating immature sporangium with the formation of endospore walls;* **(e)** *immature endospores formed on inner sporangial wall, maturing centripetally (upper half of figure) or formed at the center of the sporangium, maturing centrifugally;* **(f)** *mature sporangium and matrix containing mature endospores with EDBs, departing through annulus and pore;* **(g)** *mature endospore with EDBs;* **(h)** *endospore with disappearing 'nutritive spherules' (Ashworth 1923);* **(j)** *endospore liberated after dissolution of wall of 'spore morula' (Tirumurti 1914);* **(k)** *free endospore*

Shrewsbury 1933; Savino and Margo 1983; Noor-Sunba and al-Ali 1989; Mendoza et al. 1999), indicating a centripetal direction of maturation. Mature endospores may also be seen laterally (Figure 6); their location at the pore end of the sporangium (Beattie 1906; Ingram 1910; Tirumurti 1914; Ashworth 1923) is probably in preparation for their discharge through the sporangium's exit pore.

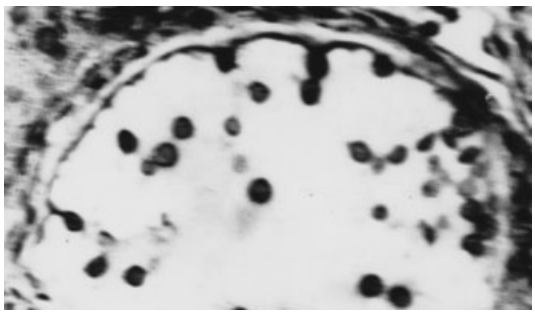

Figure 5 *Intermediate thick-walled sporangium with formation of new endospores on inner sporangial wall. PAS stain; initial magnification ×400*

The mature endospores are spherical, measuring approximately 10–12 μm in diameter. Vanbreuseghem (1973) described endospores in Indian rhinosporidial tissue to be larger than those in African tissue. Endospores have a thick wall that is PAS positive (Figure 7) and contains chitin (Karunaratne 1964), as do fungi. Ultrastructurally, they were found to have a fibrillar coat (Figure 8, Arseculeratne et al. 1999, unpublished data) which, on an analogy with the fimbriae of gram-negative bacteria, could mediate the hemagglutination of red blood cells and adherence to mammalian cells (HEp-2) in culture, described below. The finely granular cytoplasm contains a vesicular nucleus. The most striking microscopical feature is the presence of several spherical bodies of approximately 1–1.5 μmin diameter; these include the EDBs (see Contents of endospores, below). Immature and mature endospores (see Figure 6), some of which appear to be degenerate, are present in mature sporangia (see Table 3).

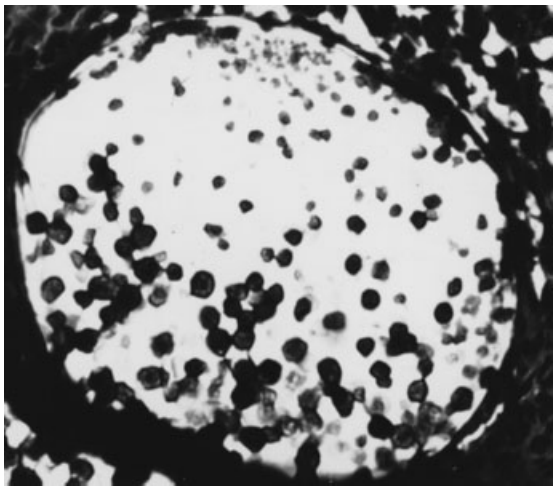

Figure 6 *Mature sporangium with atypical walls, containing mature endospores adjacent to the sporangial wall, with immature or degenerate endospores on the opposite side. H&E; initial magnification ×400*

Kutty and Teh (1975) described the endospore as having a prominent Golgi apparatus, endoplasmic reticulum, mitochondria, vacuolated spaces in the cytoplasm with an irregular plasma membrane, and the EDBs.

We have not detected motility of endospores in wet mounts of material from nasal or palpebral rhinosporidiosis; flagella or organs of motility were not seen on scanning electron microphotographs of endospores from different patients (Arseculeratne et al. 2002, unpublished data). The scanning electron microphotographs of Noor-Sunba and al-Ali (1989) also do not reveal flagella or organs of motility on the endospores; nor did Kutty and Teh (1974) note flagella on the sporangia.

Beattie (1906) described free endospores as having residual matricial material from the sporangium, which

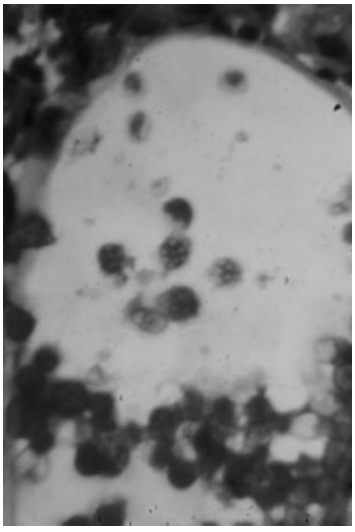

Figure 7 *Mature endospores with PAS-positive walls and internal EDBs. PAS stain; initial magnification ×400*

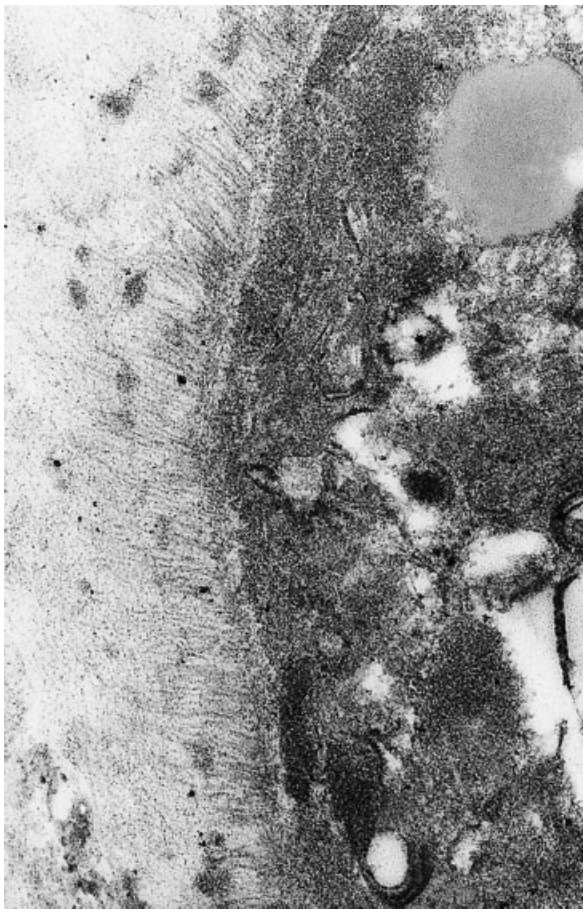

Figure 8 *Electron photomicrograph of endospore showing fibrillar coat.*

appears as an envelope around the endospore and trailing off, giving the appearance of a '. . . tail to a comet, the head being the spore-morulae' (endospore). It was pointed out (Arseculeratne 2000a) that in cytodiagnosis of rhinosporidiosis from smears, especially from nasopharyngeal sites, the residual cytoplasm of the epithelial cells (Figure 9a) could mimic the tail-like mucoid, matricial material around the endospore (Figure 9b). The rhinosporidial endospores with the mucoid covering could be distinguished from epithelial cells by the PAS stain as the nuclei of the latter do not stain magenta with this procedure, whilst the endospore stains strongly positive.

Contents of endospores: the electron-dense body

The most controversial morphological elements of *R. seeberi* are the electron-dense bodies (EDB). They are the most prominent inclusions of the endospores, and are 1–1.5 μm, spherical bodies appearing in clusters (Shrewsbury 1933) of 15–20 EDBs. Kennedy et al. (1995) described their ultrastructural features as 'irregular membrane-bound, vacuolated structures of various

Table 3 *Morphological characteristics of rhinosporidial sporangia*

Sporangium	Characteristics
Juvenile	6–10 μm in diameter Unilamellar, PAS-positive, mucicarmine and GMS-negative wall Fibrillar or granular, PAS-positive, mucicarmine and GMS-negative cytoplasm Chromatin present as a single nucleus or as multiple nuclei, each within a vesicle Laminated bodies present Lipid globules present
Intermediate	100–150 μm in diameter Bilamellar wall, inner cellulose, PAS- and mucicarmine-positive Outer wall PAS-, mucicarmine- and GMS-negative No organized nucleus, lipid globules present Mature endospores absent
Mature	100–450 μm in diameter Thinner bilamellar outer wall Inner wall PAS- and mucicarmine-positive, GMS-variable Outer wall PAS-, mucicarmine- and GMS-negative Immature and mature endospores present, embedded in matrix Mature endospores with lipid globules and electron-dense bodies

GMS, Gomori's methanamine silver; PAS, periodic acid–Schiff.

sizes containing electron-dense granular material.' Their periphery stains deep magenta with the PAS stain (Figure 7) and they can be clearly seen in smears or wet mounts of the mucoid discharge on rhinosporidial growths (Figure 10). The EDBs have also been seen in the endospores in rhinosporidial tissue of dogs (Easley et al. 1986).

The EDBs have been shown to be yellow-fluorescent with acridine orange, Feulgen-positive and DNAase-sensitive (Vanbreuseghem et al. 1955; Lakshmanan et al. 1978; Savino and Margo 1983; Moses et al. 1991). We noted that these bodies when released by ultrasonic treatment of Percoll-purified endospores or in their native location within endospores, fluoresced yellow

with acridine orange, suggesting the presence of nucleic acid; acridine orange, however, is also claimed (Chayen and Bitensky 1991) to stain mast cell granules, cartilage matrix (red fluorescence), keratin (red fluorescence), vascular elastic elements (yellow fluorescence), but these elements have not been described in EDBs.

Lakshmanan et al. (1978) concluded from histochemical tests that the EDBs stained deeply with bromophenol blue, indicating that their contents are proteinaceous, as are the walls which also stain positively with Bismark Brown; deep staining of the wall of the EDB with Sudan Black B was interpreted as indicating that the wall of the EDB had lipoprotein. The EDB also stained deeply with methyl green and was Feulgen-positive. These workers concluded that: '. . . the spherule is made up of a lipoprotein coat with a protein matrix and a strongly Feulgen-positive centre' and that the EDB does contain deoxyribonucleic acid; they cite Vanbreuseghem et al. (1955) as also having demonstrated DNA in the EDB. Beattie (1906) had also suggested that the EDB are indeed the 'spores' and describes them as containing a 'well-defined nucleus which reacts to the chromatin stains.' Minchin and Fantham (1905) noted 'a central spot' in the 'refractile granule' (EDB), which stains with hematoxylin and concluded that it is 'a chromatic nucleus.' Teh and Kutty (1975) concurred with this view. Karunaratne (1964) noted that Vanbreuseghem et al. (1955) considered the EDB to be active bodies, the actual spores; this interpretation would then mean that the 'spore' of Ashworth (1923), now named the endospore, is really a collection of the ultimate true spores and hence meriting the term 'spore-morula' used by Beattie (1906) and Tirumurti (1914).

Kutty and Gomez (1971) recognized that '. . . one of the interior ''spherical bodies''' shows 'a smaller and darker sphere enclosed within it . . .'; this 'would appear to represent a nucleus with a nucleolus.' This view is compatible with our observation that when the next stage of development, the juvenile sporangium, occurs, only one larger spherical body or very rarely two, appears within the juvenile sporangium (Figure 11). If this interpretation is correct, it would imply that this EDB is the ultimate generative, infective unit of *R. seeberi* as these and other authors have concluded. Lakshmanan et al. (1978) came to a similar conclusion: '. . . the spherules could be the initial inciting agent of the disease.'

We have found that endospores from fresh, unfrozen homogenates of rhinosporidial tissues stained deeply purple-blue in the cytoplasm and the EDBs with 3-[4,5-dimethyl thiazol-2-yl]-2-5-diphenyl tetrazolium bromide (MTT) (Figure 12; Arseculeratne and Atapattu 2003a). This dye is used in tests of the viability of diverse cells in culture (as in lymphoproliferative assays on lymphocytes – Mosmann 1983), yeasts, and mycelial fungi. The formation of the purple-blue colored formazan from MTT is due to the reduction of MTT by mitochondrial dehydrogenases and this phenomenon in the EDB, while being also shown in the endospore's

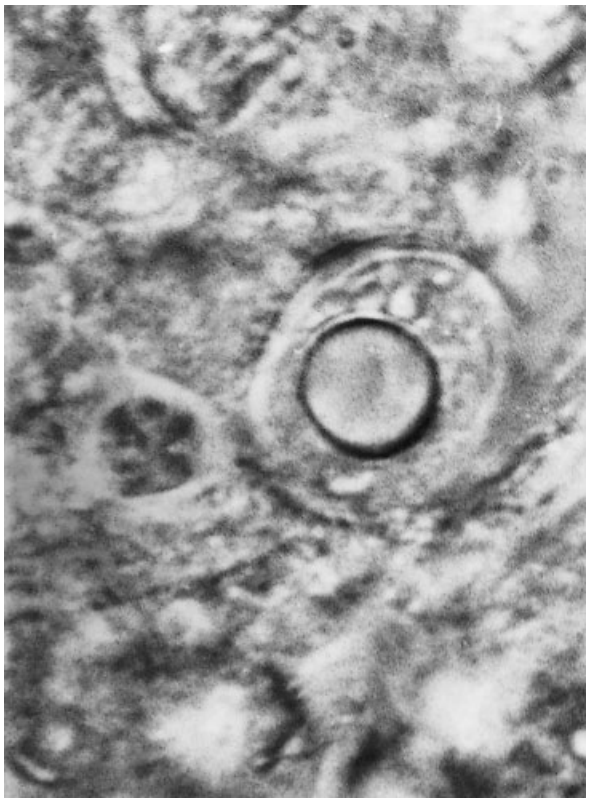

Figure 11 *Developing endospore in prejuvenile sporangium stage, showing single body (probably an EDB) which will develop into a juvenile sporangium. Wet mount of endospores in suspension; initial magnification ×1 000.*

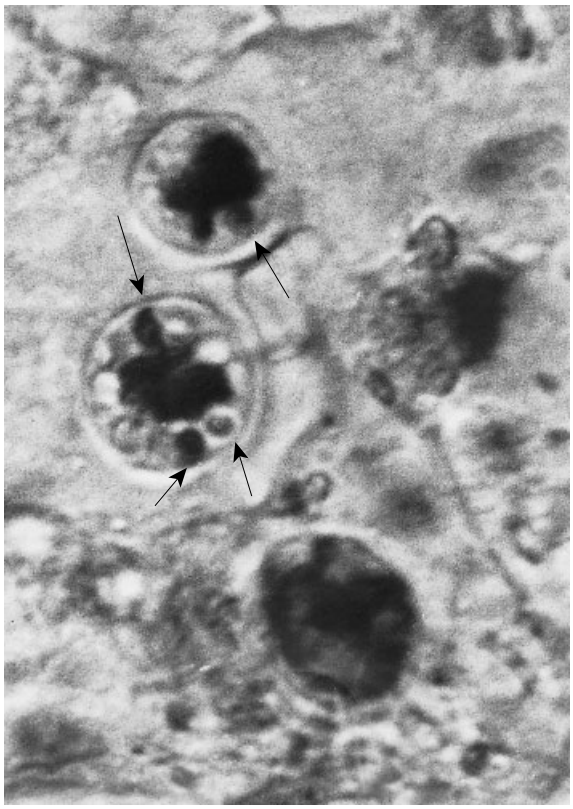

Figure 12 *Fresh endospores after incubation with MTT showing deep (purple-blue) staining of cytoplasm, and spherical internal bodies (arrows), probably EDBs. Other bodies of similar shape and size are MTT-negative and could be the protein nutritive spherules of Ashworth (1923) or the lipid bodies of Kennedy et al. (1995); initial magnification ×1 000*

cytoplasm (which contains mitochondria as described by Kutty and Teh 1975), would therefore indicate vital activity in these sites. If this conclusion is valid, then it is further evidence that the EDBs are indeed viable units.

These conclusions on the generative function of the EDB differ from those of Ashworth (1923) that the EDB are proteinaceous nutritive reserves; Shrewsbury (1933), too, disputed Ashworth's view. Easley et al. (1986), on the other hand, agreed with Ashworth (1923) that the EDBs are reserve bodies rather than mere 'protrusions of a morula-like cell wall of the spore' (Bader and Grueber 1970) or germinative bodies (Teh and Kutty 1975).

A basic question therefore, which needs resolution through an experimental model of pathogenicity, is what is the ultimate generative unit of *R. seeberi*? Is it the endospore, as most authors have assumed, or is it the EDB?

Other contents of the endospore

Eosinophilic, lipid globules were described (Kennedy et al. 1995) in the cytoplasm of the mature endospore and were regarded as nutritive reserves; they were absent in immature endospores. Some spherical bodies that do not stain with MTT (Figure 12) could be the protein nutritive bodies postulated by Ashworth (1923) or the lipid bodies described by Kennedy et al. (1995). In correlation with MTT-stained endospores, transmission electron microphotographs (Figure 13) also revealed the EDBs that possessed an electron-dense core bounded by a thick electron-dense wall, in contrast to other bodies, perhaps the nutritive (protein or lipid) bodies that were electron-lucent and without a wall.

SPORANGIA

Table 3 summarizes the principal morphological features of *R. seeberi*'s sporangia. These, of varying size and shape and in various stages of development, are abundant in most rhinosporidial tissues. Sporangia were classified according to their maturity by Kennedy et al. (1995).

The juvenile sporangium (formerly, the trophocyte)

This developmental stage is the least controversial, and has been identified free in the stroma of infected tissue or even within mature sporangia (Karunaratne 1964). It is a thin-walled sphere of 10–15 μm diameter in its early stages (Figure 14), enlarging to about 100 μm (Bader

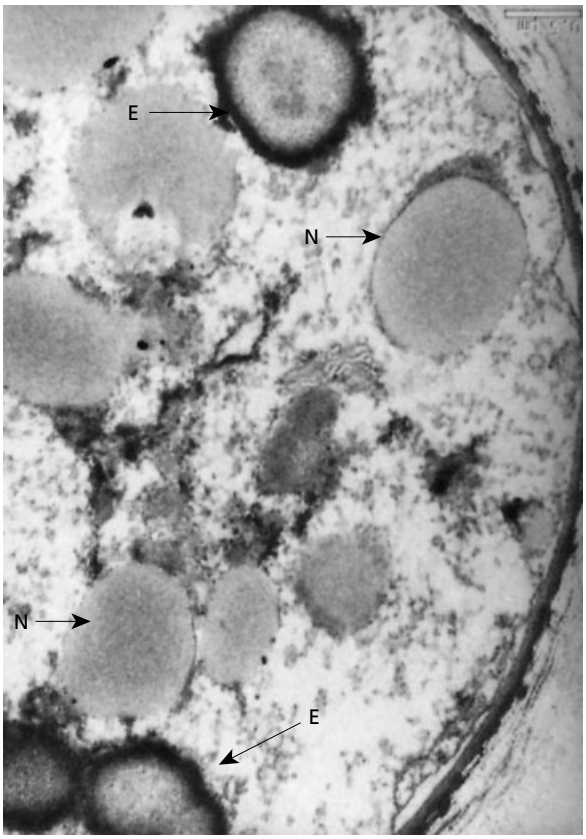

Figure 13 *Transmission electron microphotograph of Percoll-purified mature endospore showing EDBs with a relatively thick wall (E) and electron-lucent bodies, perhaps nutritive bodies without such walls (N); initial magnification × 16 000*

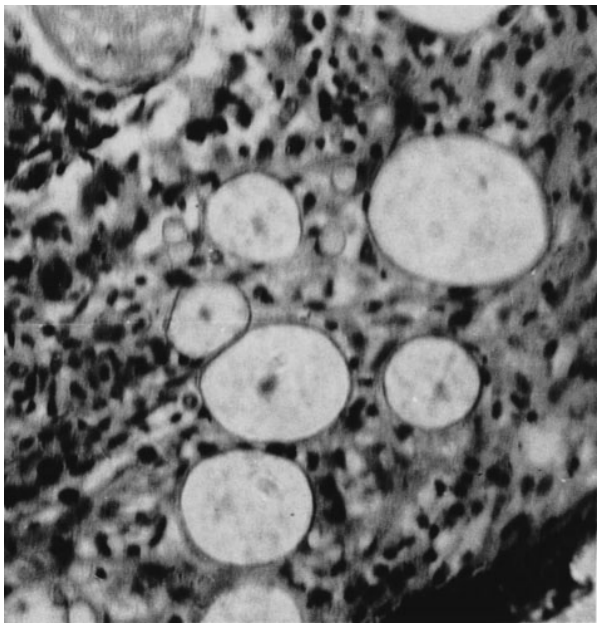

Figure 14 *Thin-walled, early juvenile sporangia, each with a single nucleus and granular cytoplasm. H&E; initial magnification ×400*

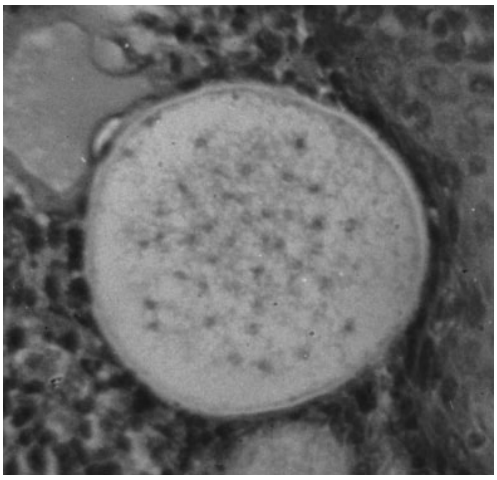

Figure 15 *Juvenile sporangium in the stage of nuclear division. H&E; initial magnification ×400*

and Grueber 1970; Savino and Margo 1983; Kennedy et al. 1995). Bader and Grueber (1970) found its wall to be laminated and that, histochemically, it consisted of a 'chitinous membrane incorporating PAS-positive neutral polysaccharides of a hemicellulose character.' It has variable intracelluar appearances according to its stage of development. Kutty and Teh (1975) recognized early, intermediate, and late stages of the juvenile sporangium.

The chromatin is either organized into a prominent single nucleus (Figure 14) with a nucleolus (Kutty and Teh 1975), or may be fragmented and diffuse (Tirumurti 1914). Kennedy et al. (1995) observed 'an aggregate of clumped and granular electron-dense material . . . and an interrupted double layered nuclear membrane . . . as the only nuclear remnants identified.' When the juvenile sporangium is about 50–60 μm in diameter, nuclear division (Figure 15) results in the appearance of chromatin within the vesicles (Figure 16) (Kutty and Teh 1974; Kennedy et al. 1995).

Kennedy et al. (1995) described ocular rhinosporidiosis in swans in which juvenile sporangia had unilamellar walls ranging from 2.4 to 9.9 μm in thickness and the wall was of electron-dense material which merged with the outer capsule of 0.9–1.5 μm thickness, which consisted of fibrils and hazy electron-dense material. This outer layer was considered in other descriptions as the outer of a bilamellar wall. In later stages, the filamentous structures are replaced by a 'faint encapsulation.' Kutty and Teh (1975) noted the similarity of the radiating structures on the surface to structures on the surface of *Cryptococcus neoformans* and suggested that this appearance was 'additional evidence in support of its (*R. seeberi*'s) fungal nature . . . .' The pitfalls of using morphological similarities in taxonomy have been pointed out earlier in this discussion in relation to the phenomenon of 'morphological convergence' in fungi.

The granular or fibrillar cytoplasm (Kennedy et al. 1995) contains endoplasmic reticulum, mitochondria, lipid globules, membrane-bound vacuolated structures containing electron-dense material that stained positively with the Feulgen stain, and microbodies that are probably nutritive in nature and are used up as the juvenile sporangium matures. Laminated bodies, with two or more concentric rings surrounding a core, ranging from 1.4 to 2.6 μm were also noted throughout the cytoplasm.

The intermediate sporangium

Intermediate (immature) sporangia (Figure 17) are spherical bodies that measure approximately 100–150 μm in diameter. Kennedy et al. (1995) identified a bilamellar wall with an overlying, third capsular layer which thinned as the sporangium matured. Thianprasit and Thagernpol (1989) described this stage to possess a trilaminated wall that included an outer capsule of a 'myriad of curvilinear structures;' the capsule was considered to be the third layer – hence trilamellar. Some descriptions of intermediate sporangia exclude this layer in recognizing the sporangium's wall to be bilamellar. The subcapsular, outer chitinous layer is thicker than the capsular layer and is similar, structurally, to the unilamellar wall of the juvenile sporangium. The new inner layer, probably of cellulose, is electron-lucent and thinner, and is formed when the sporangium is about 100 μm in diameter. The intermediate sporangium contains immature endospores in the cytoplasm that is granular or fibrillar. An intermediate sporangium that is about 140 μm in diameter is said to contain several thousand endospores (Ashworth 1923). Laminated bodies have also been noted in the intermediate sporangia.

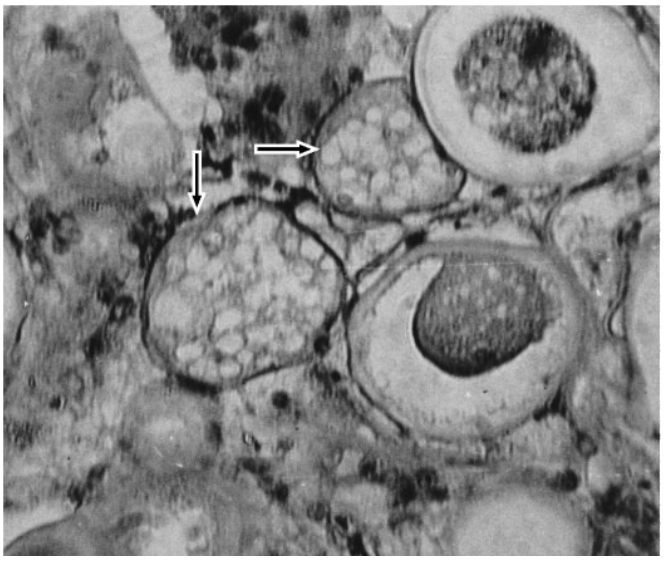

Figure 16 *Juvenile sporangia (arrows) with vesicles, after nuclear division. H&E; initial magnification ×400*

The mature sporangium

This spherical body measures approximately 150–400 μm in diameter, and is located in the stroma of the rhinosporidial polyps, as well as intraepithelially (Figure 18) and in downgrowths of the squamous epithelium into the subepidermal tissue (Figure 19).

The mature sporangium has a trilamellar (Savino and Margo 1983) wall that is thinner (1–3 μm) but is similar, tinctorially, to that of the intermediate sporangium. The outer wall contains chitin, whilst the inner wall has cellulose (Ashworth 1923; Shrewsbury 1933; Karunaratne 1964; Jain 1967), and is more translucent. The possession of chitin is a property that is shared with the fungi; the presence of a chitin-synthase gene in *R. seeberi* was reported by Herr et al. (1999a). Striations of the inner sporangial wall were noted by Beattie (1906) and by Ashworth (1923), although their existence was disputed by Minchin and Fantham (1905), and by Kutty and Teh (1974). A specialized, thickened (15 μm) area of the sporangial wall is the annulus (Figure 20) which surrounds the exit pore (Beattie 1906; Ingram 1910; Tirumurti 1914; Ashworth 1923; Karunaratne 1964; Grover 1970; Mendoza et al. 1999), which is the aperture through which the endospores are extruded.

When the sporangium matures, the wall becomes thinner while the annulus surrounding the pore remains thick (Figure 20). With maturation, the bilamellar (Savino and Margo 1983; Thianprasit and Thagernpol

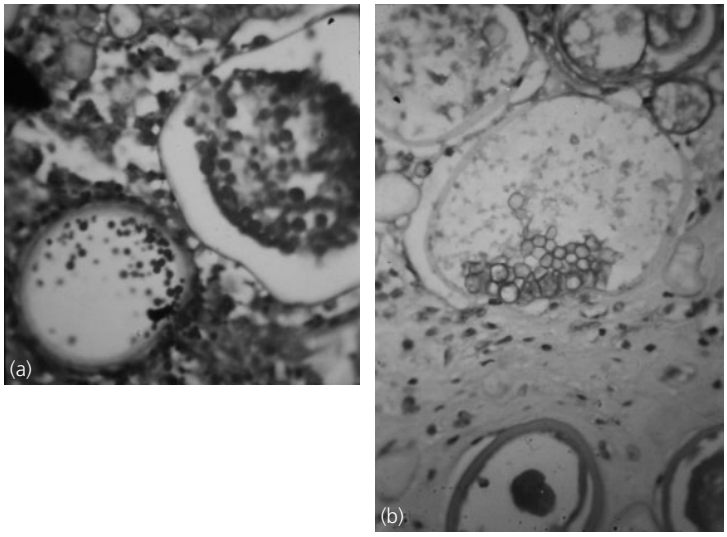

Figure 17 (a) *Intermediate (thick-walled) and mature (thin-walled) sporangia in rhinosporidial tissue. PAS stain; initial magnification ×400.* **(b)** *Intermediate, thick-walled sporangium with new formation of endospores on inner wall. PAS; initial magnification ×400*

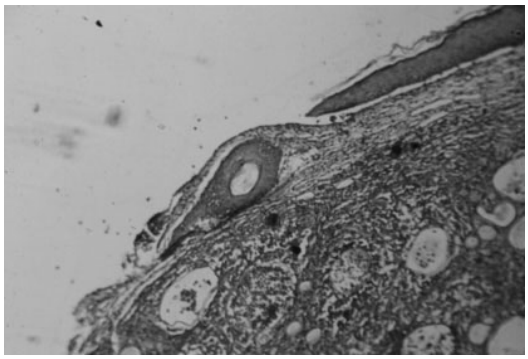

Figure 18 *Intraepithelial effete, thick-walled sporangium in subcutaneous rhinosporidiosis. PAS; initial magnification ×200*

1989) wall retains filamentous radiations or 'curvilinear tubular structures' on the outer surface; the 'dense network of threads' in the cell wall was thought to consist of cellulose (Bader and Grueber 1970).

The sporangial walls are PAS-positive as are the walls of the endospores, while also staining with Alcian Blue, indicating the presence of acid mucopolysaccharides; other tinctorial properties were described by Rao (1966) and Jain (1967). PAS-positivity decreases with maturation of the sporangial wall (Jain 1967). Rao (1966) and Jain (1967) considered the presence of acid mucopolysaccharides to confer selective permeability to nutrients, on the sporangial wall. It is relevant that Mendoza et al. (1999) postulated that sporangia apparently absorb nutrients through the walls during the active process of extrusion of the endospores. Extensive histochemical studies on the different developmental stages were also made by Bader and Grueber (1970).

The walls of degenerate sporangia could have very thick, homogeneous walls (Beattie 1906; Karunaratne 1964), or the wall could be absent, and when the sporangium is empty of endospores, it could pose a diagnostic problem in histopathology (Arseculeratne et al.

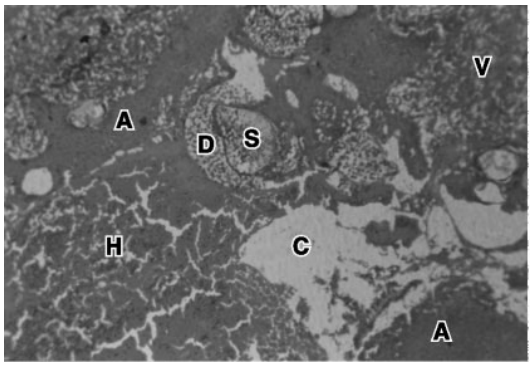

Figure 19 *Degenerate sporangium (S) in nasal rhinosporidiosis; it is encircled by ancanthotic squamous epithelium (A) surrounded by dense cell infiltrate (D), in vascular stroma (V) with hemorrhage (H) and cystic spaces (C). H&E; initial magnification ×400*

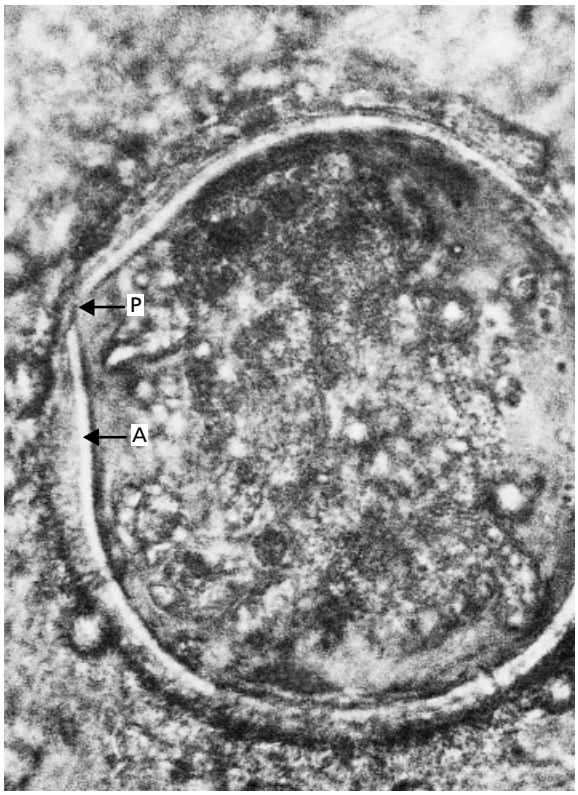

Figure 20 *Intermediate sporangium with annulus (A) and pore (P). Wet mount; initial magnification ×400*

2001). Empty, degenerate sporangia may collapse on themselves, giving characteristic linear markings that represent infoldings of the wall. A homogeneous, eosinophilic, vacuolated material sometimes fills the empty sporangia (Figure 21; Jimenez et al. 1984). Degenerate sporangia could be seen to have within them infiltrates of host-inflammatory cells (Figure 22) and multinucleated giant cells (Figure 23).

Herr et al. (1999b) reported that *R. seeberi* possesses mitochondria with flat cristae, a finding that contrasted with that of Fredricks et al. (2000). However, recently Mendoza et al. 2001a) presented new evidence that supports Herr et al.'s (1999b) observations. The presence of mitochondria with flat cristae in *R. seeberi* is also in agreement with the presence of mitochondria with flat cristae in the other members of the Order Dermocystida (the Rosette Agent and *Dermocystidium*).

Ashworth (1923) estimated that a mature sporangium contains about 16 000 endospores, many of which fail to mature and then appear morphologically and tinctorially abnormal.

The mature endospores within a mature sporangium are embedded in an intrasporangial matrix and appear spaced (Figure 24). The matricial mucoid material stains with Alcian Blue, suggesting the presence of mucopolysaccharides (Savino and Margo 1983; Thianprasit and Thagernpol 1989) that were considered as

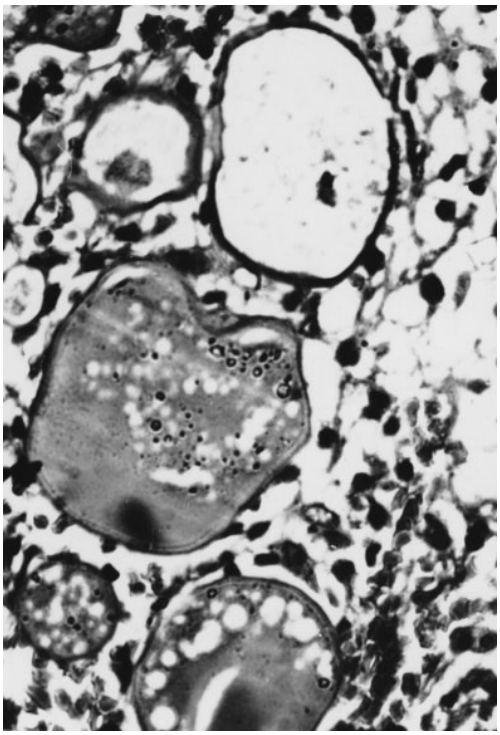

Figure 21 *Degenerate, thin-walled sporangia that are empty or contain vacuolated, homogeneous eosinophilic material; nasal rhinosporidiosis. H&E; initial magnification ×400*

inhibitors of phagocytosis of *R. seeberi* in the host tissue (Thianprasit and Thagernpol 1989); it was also thought to inhibit the penetration of drugs (Woodard and Hudson 1984). Residual portions of this mucoid material might be represented by an envelope on the endospores that leave the sporangium; this matricial residue might also appear as the 'tail of a comet' (Beattie 1906; Figure 9b), and show intense staining in immunofluorescence tests (Atapattu et al. 1999), suggesting the high antigenicity of this material. Smears of crushed polyps reveal the endospores in masses embedded in the

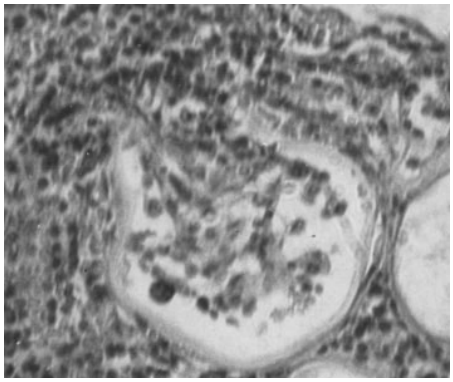

Figure 22 *Invasion of an effete sporangium by fibrocellular stromal tissue in a submental rhinosporidial mass in disseminated rhinosporidiosis. H&E; initial magnification ×400*

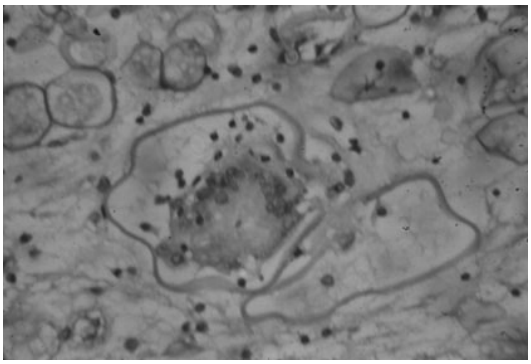

Figure 23 *Degenerate sporangium invaded by a multinucleated giant cell. PAS; initial magnification ×400*

mucoid matrix or individually as unenveloped bodies (Figure 25). The role of the matrix in the release of endospores is referred to below.

The large, 400–450 μm, subepithelial mature sporangia give the typical strawberry-like appearance to the rhinosporidial polyps, the surface of which is studded with yellow, pinhead-sized spots representing the sporangia.

The sporangia of *R. seeberi* could resemble the spherules of *Coccidiodes immitis* but can be differentiated from the latter by being larger, having thicker walls, and with more numerous endospores and an exit pore. The sporangium of *R. seeberi* also differs in staining with

mucicarmine, unlike those of *C. immitis* (Kwon-Chung and Bennett 1992).

Release of endospores from sporangia

Before extrusion, mature endospores are relocated close to the pore. The mature sporangium's pore is surrounded by a thickened annulus of the sporangial wall (Figure 20), through which the endospores are extruded into the surrounding tissues to perpetuate the 'life cycle' of *R. seeberi.* de Mello's (1954) review included a figure (Figure 23) that illustrated a lid or operculum that closed the pore; a 'film' or 'thin disc' covering the pore was also referred to by Ashworth (1923) and by Karunaratne (1964). A pore might not be visualized in some sections of tissue (see Bader and Grueber 1970); this is attributable to the plane of sectioning of the sporangium falling outside the level of the pore.

It had been been assumed that the escape of endospores resulted from rupture of the sporangium from external tissue pressure (Bader and Grueber 1970) or from within the sporangia (Ashworth 1923; Karunaratne 1964) with the endospores being 'shot-out' from the sporangium after its rupture (Beattie 1906) or after the 'thin film over the pore gives way' (Ashworth 1923). Evidence, also documented on a video recording, was produced for the operation of an active, vital mechanism, probably osmotic, for the extrusion of the endospores (Mendoza et al. 1999). de Mello (1954), too, postulated an osmotic mechanism. The endospores are extruded in an orderly procession (Figure 26) and not explosively, *en masse*, through the exit pore.

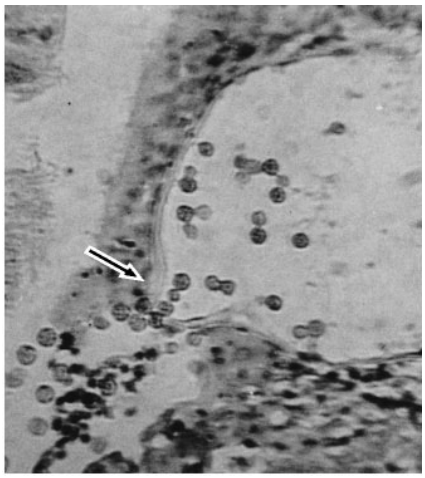

Figure 26 *Mature sporangium in nasal rhinosporidiosis with mature endospores exiting through the annulus and pore (arrow). H&E; initial magnification ×400*

Isolation and purification of developmental stages

The inability to obtain pure preparations of the developmental stages of *R. seeberi*, free of contamination with tissues of the host or with environmental microorganisms, has been the cause of the lack of unequivocal observations and firm conclusions on the biology and immunology of the pathogen, as well as on immunity mechanisms in diseased hosts. Crude preparations of rhinosporidial bodies, derived from homogenized polyps, have been used after sedimentation, coarse filtration, or pipetting-out from the homogenates. These preparations have probably had contamination from host material and the use of such crude 'antigens' could have led, for instance, to the identification of 'rhinosporidial antigenemia' on immunoprecipitation in gel-diffusion tests (Chitravel et al. 1982). It is more likely that the precipitin reactions that were observed were between contaminating human antigens and the corresponding antibodies from the animal sera which were obtained by immunization against these crude rhinosporidial preparations derived from human tissue.

A method was described (Atapattu et al. 1999) for the isolation, in the pure state, of the different developmental stages of *R. seeberi*, from homogenates of rhinosporidial tissue. This method is based on centrifugation of deposits of tissue homogenates, in density gradients of Percoll (Figure 27). The EDBs may be obtained by controlled disintegration of the endospores by ultrasonic or enzymic (chitinase) means. PAS-stained smears of chitinase-treated suspensions of endospores (calcium phosphate buffer at pH 6) showed that the intensity of PAS positivity of the endospore's wall decreased, with better visualization of their EDBs (Arseculeratne 2002, unpublished data).

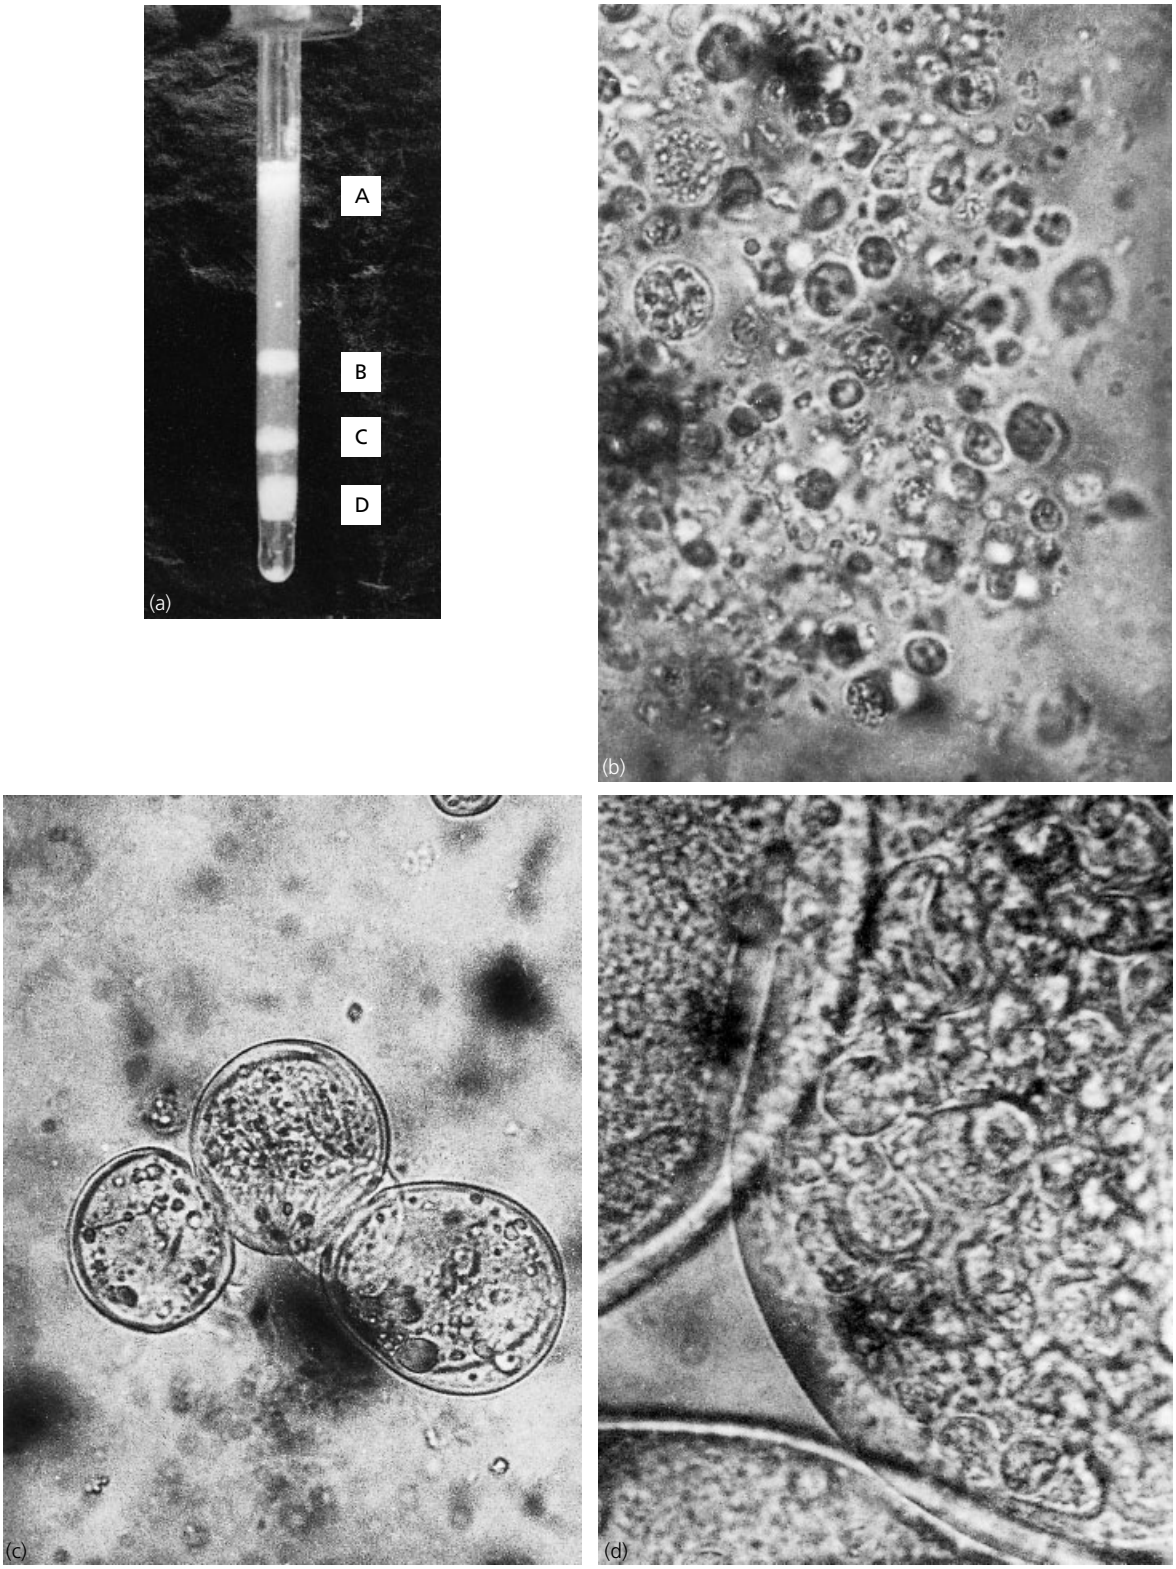

Figure 27 (a) *Fractionation of homogenate of rhinosporidial tissue in Percoll of graded density. A, small endospores; B, larger endospores; C, juvenile sporangia; D, intermediate sporangia. Mature sporangia were not visualized, probably after rupture.* **(b)** *Small and large endospores after fractionation in Percoll. Wet mount; initial magnification ×400.* **(c)** *Juvenile sporangia after fractionation in Percoll. Wet mount; initial magnification ×400.* **(d)** *Intermediate sporangia after fractionation in Percoll. Wet mount; initial magnification ×400.*

When aseptic conditions are used in the Percoll purification, the isolated rhinosporidial bodies are free even of bacterial contamination. These preparations would permit investigations, particularly on the immunology and experimental pathogenicity of *R. seeberi*.

VIABILITY OF ENDOSPORES

The question of the viability of the endospores, in homogenates that have been stored at low temperatures or after purification in Percoll, and used for inoculation of the test animals, is a problem that has a bearing on experiments on the pathogenicity of *R. seeberi*. Homogenates of human or animal rhinosporidial tissues have been used by many workers to attempt infection of experimental animals. With congenitally immunodeficient mice (Arseculeratne et al. 2000), the homogenate was mixed with sonicates of Percoll-purified endospores with their ultrasonically liberated EDBs. With the inability to culture *R. seeberi*, in vitro, and the absence of a method for the direct assessment of the viability of these bodies at the time of experimentation, the viability of the endospores and sporangia was assumed in all these experiments. Nigrosin-eosin or nigrosin-neutral red was found to be useful in determination of viability through non-uptake of the dye (Jain 1967). Arseculeratne and Atapattu (2003a) described the use of Evan's blue in a simple test for the assessment of the morphological integrity of *R. seeberi*'s endospores; it is based on their staining by the vital dye Evan's blue (Figure 28); unfrozen, fresh endospores were also found to stain deeply (purple-blue) with MTT (Figure 12; Arseculeratne and Atapattu 2003a), which is used to assess the viability and hence proliferation of lymphocytes in lymphoproliferative assays for cell-mediated immune competence, and for assessing the viability of fungi. Endospores, after autoclaving, formalinization, and trypsinization, failed to take up the Evan's blue or MTT, whilst endospores from freshly homogenized human rhinosporidial tissue stained deeply, in its cytoplasm and EDBs. *Toxoplasma* behaves in a similar manner in the Sabin–Feldman test (Sabin and Feldman 1948) when dead cells fail to stain with methylene blue. Purified endospores after prolonged storage at –20°C retained their staining with Evan's blue but failed to stain with MTT (Arseculeratne and Atapattu 2003a). Apparently, staining with Evan's blue reveals the morphological integrity of the endospores, especially the EDBs, whilst MTT staining indicates their viability on account of the need for enzymic mechanisms (mitochondrial in eukaryotic cells) to reduce the MTT to the purple-blue colored formazan.

Biological activities of endospores

HEMAGGLUTINATION

Percoll-purified suspensions of endospores from human rhinosporidial tissues were found to cause hemagglutination of red blood cells from humans, a species that is susceptible to infection with *R. seeberi*, and from rats (Figure 29), that have not been reported as susceptible; the hemagglutination occurred as well at 37°C as at 4°C, and was reactivated after agitation and disruption of the clumps of hemagglutinated red cells after first incubation (Arseculeratne and Atapattu 2003b).

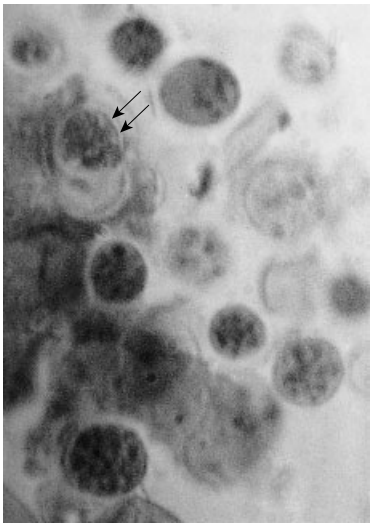

Figure 28 *Fresh endospores stained with 0.2 percent Evan's blue in PBS, showing deeply stained bodies probably EDBs, with moderately stained cytoplasm, and unstained spherical bodies (arrows); initial magnification ×1 000.*

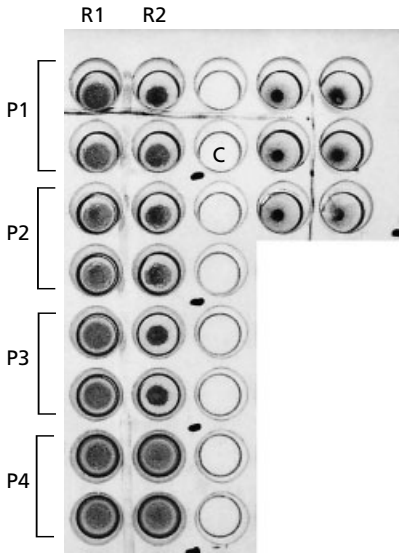

Figure 29 *Hemagglutination of rat red blood cells by purified rhinosporidial endospores. C, control red cells in PBS; R1, R2, rats from which red cells were obtained; P1, P2, P3, P4, purified endospores from four rhinosporidial patients.*

ADHERENCE

Endospores were reported to show strong adherence to epithelioid cells from a human rectal tumor, in vitro (Levy et al. 1986). Endospores also showed adherence to HEp-2 cells (derived from human laryngeal carcinoma) in culture in Minimum Essential Medium (MEM) with 10 percent fetal calf serum (Figure 30); an intriguing feature of the adherent or free endospores in mixtures with these mammalian cells was the appearance of bodies that were similar in size and shape to the EDBs on the surface of the endospore (Figure 31; Arseculeratne and Atapattu 2003b), suggesting that the EDBs were in the process of extrusion from the endospores on contact with the HEp-2 cell. Similar 'protrusions' of the endospore's cell wall were described by Bader and Grueber (1970) and by Teh and Kutty (1975), whilst the latter authors considered the protrusions to contain EDBs. The significance of this phenomenon remains to be elucidated. The HEp-2 cells that showed adherent endospores numbered only about half of the total cells present and a similar phenomenon, attributed to variations in the density of receptors for adherence on the buccal cell-surface, was reported for *Candida albicans* (Sandin et al. 1987).

It was previously pointed out (Atapattu et al. 2000) that the endospore had a fibrillar surface as revealed on transmission electron microscopy (Figure 8), which might, on a parallel with the adhesive fimbriae of gram-negative bacilli, be the agent responsible for the adherence to mammalian cells and for hemagglutination.

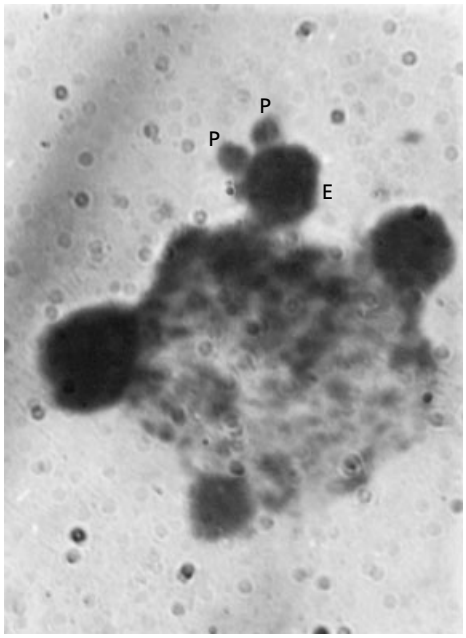

Figure 30 *Adherence of purified endospores to HEp-2 cells in MEM with 10 percent fetal calf serum. One endospore (E) has two protrusions (P) suggestive of extruding EDBs. PAS stain; initial magnification ×1 000.*

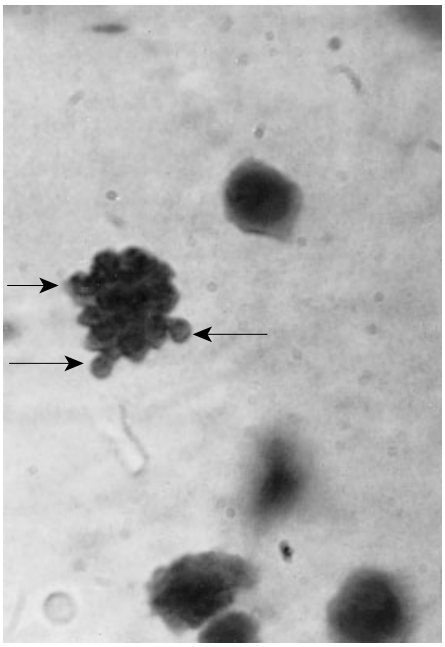

Figure 31 *Protruding bodies (arrows), compatible in size and shape with EDBs, attached to endospore in suspension with HEp-2 cells. PAS; initial magnification ×1 000.*

Sensitivity of *R. seeberi* to antimicrobial drugs and biocides

On account of the inability to culture *R. seeberi* in vitro, conventional tests of sensitivity to antimicrobial drugs and to biocides have not been possible with *R. seeberi*. There have been many agents that were tested clinically. Quinine hydrochloride (Wright 1922), salts of antimony and bismuth, iodine, and pentamidine (Rajam et al. 1955) griseofulvin, amphotericin B, and topical steroids (Jimenez et al. 1984; Ho and Tay 1986), local and systemic antibacterial antibiotics and radiotherapy (Satyanarayana 1966) were clinically ineffective, as were other compounds (see de Mello 1954). Allen and Dave (1936), discussing the treatment of rhinosporidiosis, recorded negative results in therapy with a variety of other compounds. The only agent that is now used in therapy is dapsone (4,4'-diaminodiphenyl sulphone, DDS), and the evidence for its efficiacy was obtained from clinical observations and microscopic examination of the pathogen in rhinosporidial tissue from treated patients (discussed under Treatment below). Since leprosy, which also occurs in the same regions of rhinosporidial endemicity (in Sri Lanka), is also treated with this drug, an alternative drug for rhinosporidiosis will be advantageous, in the event of the development of resistance of *Mycobacterium leprae* to dapsone. An additional justification for an alternative drug is that dapsone precipitates hemolytic crises in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, which is common in the regions of rhinosporidial endemicity in Sri Lanka.

The development of sporangia from endospores in aqueous suspension under storage (described under in vitro culture, below) was used in an attempt to test the sensitivity of *R. seeberi* to various drugs in vitro (Arseculeratne 1999, unpublished data). Viability of *R. seeberi* was deduced from the formation, over a period of 1–2 weeks, of juvenile sporangia of at least 50 µm in diameter as observed microscopically in flat-bottomed wells of cell culture trays. It was difficult to standardize the optimum conditions for sporangial development from the endospores, and the method was abandoned. A further disincentive to pursue this technique was the long period of observation required; the development of sporangia from endospores, or 'maturation' as Easley et al. (1986) termed the phenomenon, was noted to be upto 35 days while Grover (1970) noted the development within 10 days.

The Evan's blue test of the morphological integrity of endospores has been used to investigate their sensitivity to various biocides and antimicrobial agents (Arseculeratne 2002). The EDBs of untreated endospores stained intensely while the cytoplasm had a lesser intensity of staining (Figure 28). The end point used was the loss of staining of the EDBs and the cytoplasm, as in endospores that were treated with autoclaving and formalinizing. Chloroxylenol, chlorhexidine, Betadine, cetrimide, Tincture Iodine, and 10 percent formalin produced marked loss of staining with Evan's blue. Endospores treated with these agents and stained with MTT also showed a similar pattern of loss of staining (Arseculeratne 2002, unpublished observations).

CULTURE

The terms 'growth' and 'development' need definition in discussing the literature on culture of *R. seeberi*. By 'growth,' in this discussion, is meant the increase in size of a given stage, e.g. the enlargement of a sporangium. By 'development' is meant the sequential formation of the ontogenic stages, e.g. the development of an endospore into a juvenile sporangium. 'Development' may also be equated with 'maturation,' a term used by Easley et al. (1986). 'Serial propagation' refers to the repetition of the cycle of development of each stage to the mature sporangium, the release of its endospores and the repetition of the cycle. These differentiations might serve to avoid confusion in deducing from observations on the formation of sporangia from endospores in vitro, that true, cyclical development of the ontogenic stages occurred.

Culture on inanimate media

Numerous attempts are recorded in the literature as not having produced definite evidence of serial propagation of *R. seeberi*, on inanimate culture media (Shrewsbury 1933; Dhayagude 1941; Satyanarayana 1960; Reddy and Lakshminarayana 1962; Kennedy et al. 1995). A wide variety of conventional bacteriological culture media has been used unsuccessfully, sometimes with exotic additives such as horse dung, prune juice, and hydrocele fluid, and incubated under various conditions of temperature and aerobiosis. Claims have, however, been made of successful culture in inanimate media (see Karunaratne 1964), but none of these reports provided unequivocal evidence for serial propagation of *R. seeberi*, in vitro. What appears to have been interpreted as propagation was in fact the maintenance of morphological integrity and continuation of the development of the endospores for a limited period under suitable conditions such as low temperature, and an environment such as that in monolayer cultures of cells. The limited ontogenic development is not indicative of serial propagation of *R. seeberi*.

Other reports of allegedly successful culture of *R. seeberi* in vitro (e.g. the mycelial fungus of Krishnamoorthy et al. 1989) dealt with contamination by environmental microorganisms or by organisms that were confused with *R. seeberi* (e.g. *Microcystis aeruginosa* of Ahluwalia et al. 1997; Ahluwalia 1999).

Grover (1970) suspended material from human rhinosporidial tissues in the synthetic medium TC 199 at 4°C and observed a rapid increase in the number of endospores and the formation of sporangia; the organism was maintained for 4 months. No mycelium was formed. We have made similar observations with Percoll-purified endospores (Arseculeratne et al. 1996, unpublished data) in phosphate-buffered saline or in tissue culture media, although the development did not proceed beyond the stage of immature sporangia; at no stage did we observe endosporulation in, and endospore-release from, these sporangia. Various conditions, such as temperature (4 °C, room temperature ambient at 28–30 °C), bubbling of air through the suspension, alternative suspending media (distilled water, phosphate-buffered saline pH 7.2, natural ground water) were tested, but the conditions for reproducible ontogenic development are as yet obscure. This limited in vitro development has therefore been unable to provide the basis for a standardizable, reproducible method for the assay of sensitivity of *R. seeberi* to antimicrobial agents.

Growth in cell cultures

Cultures of mammalian cells have also been tested for their ability to support the serial propagation of *R. seeberi*.

Levy et al. (1986) described attempts to grow the organism from canine nasal rhinosporidiosis in monolayers of a cell line from an epithelioid human rectal tumor (HRT); they reported strong adherence of the organism 'within minutes' to the cells. They also claimed

to have observed, after 2 days, 'polyp-like structures' consisting of HRT cells and mature sporangia releasing endospores into the medium. The analogy between their polyps in cell cultures, which appeared within 2 days, and the polyps in clinical cases appears doubtful, not only in respect of the time interval of several months required for the development of the natural lesions, but also because the clinical polyps are consequent to the host's tissue response (epithelial proliferation, edema, with cellular infiltration into the fibrovascular stroma) surrounding the multiple sporangia and endospores. These authors regarded the need for contact with mammalian cells for the complete development of the pathogen, and the absence of such cells as a reason for the failure of culture of the pathogen on inanimate culture media. Easley et al. (1986) documented similar results. There was focal proliferation of the tumor cells around the organism, the numbers of which increased; the authors claimed that this 'reproduction' continued for over 3 months in subculture. No independent confirmation of these results has been reported.

Whether these observations were similar to those reported by Grover (1970) is not clear. The development of endospores into sporangia, which was earlier reported by Grover (1970), was also noted by Levy et al. (1986), who added that this development occurred also in the absence of the HRT cells.

We have observed the development of immature sporangia from endospores that were added to cultures of HEp-2 or HeLa cells in MEM with 10 percent fetal calf serum, or even in phosphate buffered saline (PBS) pH 7.2 thawed after storage at −20°C, although the formation of mature sporangia with mature endospores was not observed.

Kennedy et al. (1995), however, did not note any evidence of growth of *R. seeberi* in fresh rhinosporidial tissue, in culture media with 10 percent fetal bovine serum.

IMMUNOLOGY

Data on the immunology of the developmental stages of *R. seeberi* were unavailable until recently, attributable to the absence of a method for obtaining pure cultures of the organism in vitro. The method described above for the purification of the developmental stages of *R. seeberi* from homogenates of rhinosporidial tissue, using graded dilutions of Percoll, now permits the isolation of these stages, free of contamination from host tissue and contaminant microorganisms. EDBs may also be obtained from the endospores by controlled sonic disintegration.

Herr et al. (1999c) used immunoelectron microscopy to demonstrate an antigen that first appears immediately under the mature sporangial wall; this antigen was apparently absent in sporangia of earlier stages of maturation and in endospores. The authors stated that this was 'the first report in which an antigenic material with a potential role in the immunology of rhinosporidiosis has been detected.' This finding also suggests the occurrence of antigenic variation in *R. seeberi* that might be a means of immune evasion of this pathogen.

A further finding that is relevant to the pathogenesis of rhinosporidiosis, in particular to its chronicity, recurrence, and dissemination, is that sonic extracts of purified rhinosporidial endospores and sporangia showed evidence on immunoblots of the presence of human immunoglobulins (IgG, IgM, and to a lesser degree IgA) in the rhinosporidial antigens; this suggests that either immunoglobulins were bound to the rhinosporidial antigens or that these antigens had epitopes that cross-reacted with those on human immunoglobulins (Atapattu et al. 2000). Azadeh et al. (1994) reported the presence of IgG and IgA on walls of early and mature sporangia and in endospores; IgM was absent. This phenomenon might also contribute to immune evasion by *R. seeberi*.

The phenomenon of binding by pathogens of host proteins has also been described in bacteria (Boyle 2000) and in schistosomes (Roitt et al. 1993).

PATHOGENICITY IN EXPERIMENTAL ANIMALS

An experimental animal model of rhinosporidiosis has yet to be established. This lack has contributed to the paucity of information on immunity mechanisms in rhinosporidiosis, some aspects of the developmental 'life cycle' and the in vivo response of *R. seeberi* to antimicrobial drugs.

Rhinosporidiosis occurs in many species of farm, domestic, and wild animals. Some of these species (cats, goats, horses, bovines), conventional experimental animals (guinea pigs, mice, rabbits, rats), and other animals such as monkeys and snails, and even a human volunteer (Habibi et al. 1944, quoted by Karunaratne 1964) have been inoculated with homogenates or powdered dry material from rhinosporidial tissue, through diverse routes – subconjunctival, subcutaneous, intradermal, inreaperitoneal, intravaginal, intratesticular, as well as by scarification of the skin, buccal and nasal mucosa, and through the gills of fish, the mantle and mouth parts of snails. No sustained or progressive disease occurred (see Karunaratne 1964). The chorioallantoic membrane, yolk sac, and the amniotic cavity of developing chick embryos also failed to support growth of *R. seeberi*. On a superficial resemblance of the lesions and tissue forms produced by *R. seeberi*, to those of a *Dermosporidium* spp. in frogs, Karunaratne and Dissanaike (A.S. Dissanaike, 1995, personal communication) injected homogenized material from human rhinosporidiosis into frogs (*Rana temporaria*) but no progressive disease ensued. We have also found five genera/species of amphibia to be insusceptible to rhinosporidial

infection (Arseculeratne 1999, unpublished data). Since the frog pathogen *Dermocystidium* is now included with *Rhinosporidium* in the proposed, new Order Dermocystida of the Class Mesomycetozoea (Herr et al. 1999b; Mendoza et al. 2002), it is relevant that Carini (1940) failed to produce the disease in the frog *Hyla rubra*, with the frog pathogen.

Negative results were also produced by intraperitoneal injection of suspensions of endospores and sporangia in 5 percent hog gastric mucin or in 100 percent Percoll in mice (Arseculeratne, 2000, unpublished data).

Iatrogenically immunosuppressed animals (steroids, Jain 1967; cheek pouch of hamsters under steroids, Grover 1970; cyclophosphamide in C3H mice, Arseculeratne 1998, unpublished data; x-irradiated, Satyanarayana 1960) also proved to be insusceptible. Congenitally immunodeficient mice also failed to support the growth of *R. seeberi*; Levy et al. (1986) stated that 'aged spores' failed to produce infection in nude mice when the 'spores' were inoculated, on the scarified nasal mucosa, intramuscularly or intraperitoneally. Congenitally immunodeficient SCID and nude mice failed to support the growth of endospores, sporangia and EDBs released from endospores, purified from human rhinosporidial tissue (Arseculeratne et al. 2000).

A uniform finding in all these experiments was that the injected material showed only degenerate sporangia that were subsequently invaded by fibrous tissue, and that the endospores had disappeared in approximately 3 weeks.

The failure to establish infection might have resulted from nonspecific immunity, especially through macrophages, which might have prevented the initial establishment of infection during the first few days after inoculation, rather than from specific adaptive immune responses that would have been operative later.

A second factor that might be involved in the failure of tests of experimental pathogenicity is the viability of the rhinosporidial endospores and sporangia that were obtained from homogenized tissues. Using the MTT dye reduction test described above, we observed that Percoll-purified endospores which had been stored at −20°C for several months, failed to stain with the dye, indicating a reduction of viability (Arseculeratne and Atapattu 2003a). The age of the endospores used as inocula in the experiments reported in the literature has not been stated and the possibility remains that low viability of the endospores contributed to the negative results.

A further factor that might be absent in inocula prepared from rhinosporidial tissue is concomitant microbiota – hydrophilic microorganisms in the putative natural aquatic habitat of *R. seeberi*; it is conceivable that some of these organisms might be synergistic with *R. seeberi* as has been demonstrated of *Wolbachia* spp. with filarial nematodes, lactobacilli with *Trichomonas vaginalis*, and *Staphyococcus aureus* with *Candida albicans*.

RHINOSPORIDIOSIS

Rhinosporidiosis is an infective disease in the sense that the pathogen is detectable in the lesions in rhinosporidiosis. No evidence has, however, been adduced that it is transmissible as there has been no unequivocally documented instance of cross-infection between members of the same family or between animals and humans.

Cases have been overwhelmingly sporadic but two outbreaks have been described. In Serbia an outbreak of ocular and nasal rhinosporidiosis in 17 humans was reported by Vukovic et al. (1995), whilst Kennedy et al. (1995) described an outbreak of ocular and nasal rhinosporidiosis in captive swans in Florida, USA.

EPIDEMIOLOGY

Geographical distribution

Sporadic cases of the disease have been reported from more than 60 countries of different geographical characteristics (Table 4), although it occurs predominantly in tropical and subtropical regions. Southern India and Sri Lanka have had the highest incidence; other countries where the disease is endemic include Argentina, Brazil, USA (Texas), and Uganda. Incidence rates, even in hyperendemic countries, vary with region; in India, South India has a high incidence whereas the disease is rare in North India (Paul et al. 1978). In Sri Lanka, the predominant focus is the dry zone. The south central region in the USA is an endemic-enzootic region (Wallin et al. 2001). Karunaratne (1964) noted that ocular rhinosporidiosis (oculosporidiosis) was commoner in South Africa.

In Western temperate and Middle Eastern countries, most cases of human rhinosporidiosis occurred in expatriate Indians who probably acquired the disease in their native lands (Al-Hili 1985; Matusik et al. 1986; Mears and Amerasinghe 1992; Ohgaki et al. 1994). On account of this feature, increasing international movement of persons from countries with endemic rhinosporidiosis might result in a more frequent occurrence of rhinosporidiosis in nonendemic countries; the disease might then merit the term 'an emerging infection.' Yet a few cases of rhinosporidiosis have been reported in persons, living in the West, who have never traveled to endemic areas (Wright 1907; Weller and Riker 1930; Lasser and Smith 1976; Woodard and Hudson 1984; Gaines et al. 1996). The disease in all these cases, irrespective of the country of occurrence, has shown remarkably uniform clinical and pathological features.

Reasons for endemicity

It has also to be explained why the disease is of high endemicity in certain regions of southern India and in

Table 4 *The geographical distribution of rhinospiridiosis in humans and animals*

Region	Countries
Africa	Burundi, Cameroons, Chad, Congo, Egypt, Ethiopia, Gabon, Ghana, Guinea, Ivory Coast, Kenya, Liberia, Madagascar, Malwai, Martinique, Mozambique, Nigeria, Rwanda, South Africa, Sudan, Tanzania, Uganda, Zaire, Zambia, Zimbabwe
North America	Canada, Mexico, USA
Central America	Belize, El Salvador
Caribbean Islands	Cuba, Guadeloupe, Tobago, Trinidad
South America	Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Paraguay, Uruguay, Venezuela
Asia	Bangladesh, India, Indonesia, Japan, Laos, Malaysia, Pakistan, Papua New Guinea, The Philippines, Sri Lanka, Thailand, Vietnam
Europe	Germany, Great Britain, Italy, Latvia, The Netherlands, Poland, Russia, Serbia, Spain, Switzerland
Middle East	Bahrain, Iran, Israel, Saudi Arabia, Turkey

the dry zone of Sri Lanka. If indeed ground waters are the natural habitat, then the chemical and physical characteristics of these waters need definition. In addition, as pointed out above, other aquatic microorganisms might also be relevant to a possible synergistic action in the establishment of natural rhinosporidiosis.

Seasonal incidence

Differences of opinion exist on the seasonality of the disease. Paul et al. (1978) stated that in Jammu, India, the disease appears to be met with towards the later months of the year (see also Jain 1967). Ratnakar et al. (1992) reported a seasonal variation in ocular and nasal disease. There was no seasonal feature in other reports (Balachandran et al. 1990); indeed, in view of the slow growth of the lesions, a seasonal variation might be obscured. The time of arrival of the patients, especially farmers, at hospital might rather depend on weather and monsoons and on exigencies of occupation.

Incubation period

Rhinosporidial growths are of variable duration, from 8 days to 35 years (Allen and Dave 1936; de Mello 1954), with a shorter duration in ocular than in nasal disease (Karunaratne 1964). When a preceding event such as trauma has been noted, the incubation period has been as short as 6–16 days (Jimenez et al. 1984); more commonly it has been months or a few years. In most cases, it is difficult to estimate the incubation period on account of the slow growth of the polyps and hence clinical manifestation

Differences in race and religion of patients

From Sri Lankan data corrected for population ratios, Karunaratne (1964) recorded differences in the occurrence of nasal and ocular rhinosporidiosis between racial and religious groups; it was noted that nasal and ocular rhinosporidiosis was commoner in the Muslims with the comment that their religion 'enjoins the thorough washing out of the nose before entering the mosque for prayer, and I am given to understand that this may include the mechanical cleansing of the nostril with the finger,' an ideal scenario for the inoculation of finger-borne *R. seeberi* from the water. Hindus predominated among patients with nasal rhinosporidiosis in India (Agarwal 1966). Penile or urethral rhinosporidiosis was, however, predominant among Muslims (Tirumurti 1914). Kurup (1931) concluded that 'customs, ways, manners and sanitary conditions' were important in its etiology; in his series, the incidence was greatest among the Muslims on the west coast of India.

Occupation and socioeconomic status of patients

Occupationally, most patients, especially in the large Indian series, have been agricultural workers and persons of the lower socioeconomic strata. Of particular interest is the occurrence of rhinosporidiosis in river-sand workers (Noronha 1933; Mandlik 1937) which supports the claim that the pathogen has an aquatic habitat, with sand particles providing mucosal abrasions for its implantation. From Sri Lankan data, Karunaratne (1964) postulated an etiologic link with work that involved contact with mud in paddy fields, although the occurrence of the disease in patients without such an occupation makes this a doubtful link. Caniatti et al. (1998), reporting four dogs with nasal rhinosporidiosis, also suggested mud in rice fields as the source of the pathogen. Indian data do not support that view.

Patients have often been poor, with a low standard of living, and among them farmers and laborers predominated (Allen and Dave 1936; Elles 1941). In India, the disease was found in 'all socio-economic strata and among all communities and religious groups' (Moses et al. 1990); this is of interest on account of the putative aquatic habitat of *R. seeberi* and the suggestion that water in communal pools, which are used for ablutions before religious rites in some communities, is a vehicle of transmission.

Age and sex differences of patients

Most patients in the African, Sri Lankan (Karunaratne 1964) and Indian series (Moses et al. 1988) have been under 25 years of age, with a range from 4 months to 90 years (Sharma et al. 1962), whilst most patients were young adults (15–40 years); this feature is probably linked to occupation.

In patients under 15 years of age, nasal and ocular rhinosporidiosis occurred more frequently in females (Karunaratne 1964). In adults, a male predominance has been noted in most series, African, Sri Lankan, and Indian, although in other series (Moses et al. 1988, 1990) no sex difference was noted in the occurrence of either nasal or ocular disease. In other series, for example of 1 241 patients, 84 percent were males (Kwon-Chung and Bennett 1992). The male preponderance in older age groups was, however, not seen in younger patients. The preponderant male incidence might have an occupational basis, although the male preponderance in animal rhinosporidiosis would argue against an occupational basis for the preponderance of the disease in human males. Karunaratne (1964) noted that nasal rhinosporidiosis was commoner in males whereas ocular rhinosporidiosis was more common in females. Occupational exposure to the postulated water-borne pathogen is insufficient to explain the predominant occurrence in males, in view of the exposure of females, in one series of cases, to the same environment (Wright 1922). A male predominance has been noted in swans (Kennedy et al. 1995), as in humans, although Moses and Balachandran (1987) found no sex difference in 103 farm animals.

Sources of the pathogen

The evidence for ground waters as the natural habitat and source of *R. seeberi* is impressive:

- rhinosporidiosis in patients with a history of having bathed frequently in such waters
- the occurrence of an outbreak in persons who bathed in the same lake (Vukovic et al. 1995)
- the clustering of the disease in river-sand workers (Noronha 1933; Mandlik 1937)
- the occurrence of the disease especially in upper respiratory and ocular sites
- the occurrence of nasal and ocular disease in animals that habitually come in contact with such waters, especially the epizootic disease in swans (Kennedy et al. 1995); see also Ecology, above.

MODE OF INFECTION

Rhinosporidiosis in upper respiratory sites is thought to be initiated by the implantation of endospores from the aquatic habitat into the respiratory mucosa, aided by abrasions caused, for instance, by sand particles in river-sand workers who dive into the water (Mandlik 1937) or by vigorous cleansing of the anterior nares with the fingers (Forsyth 1924; Karunaratne 1964); it is relevant to the initiating role of abrasions caused by sand tha workers who did not enter the water, but merely worked on the river banks, did not show the disease (Jain 1967). Trauma to the nose even in the absence of exposure to stagnant water, has been recorded as an antecedent event (Weller and Riker 1930; Jimenez et al. 1984). 'Autoinoculation' of the mucosa by endospores released from sporangia or after surgery was claimed (Karunaratne 1964) to be responsible for satellite polyps in the adjacent regions. On the same basis, it has been claimed that polyps on the skin result from implantation of endospores by scratching with contaminated fingers, although the rarity of skin polyps in children who might be expected to scratch themselves as often as adults makes this explanation improbable. Polyps on the skin on the other hand could occur through hematogenous dissemination from respiratory sites; lesions on the skin, however, without precedent respiratory rhinosporidiosis have been recorded (Madhavan et al. 1978).

No clear evidence of transmission between humans, even between those living in close contact, has been recorded (Wright 1922); the disease has occurred in members of the same family, although they were not living together (Allen and Dave 1936). Karunaratne (1963) documented three cases among family members who lived together, but such an occurrence could have also been rather the result of exposure to a common source of the pathogen.

Karunaratne (1964) used the term 'transepithelial infection' to refer to the implantation of endospores through minor abrasions in the skin or mucosae, through occupationally acquired injuries, from sand particles, and vegetable matter contaminated with soil; dust laden with the endospores is thought to be the vehicle of infection in ocular rhinosporidiosis. Bader and Grueber (1970) agreed with the concept of transepithelial infection though Ashworth (1923) disputed it.

The mode of infection in ocular rhinosporidiosis is even more obscure; Kaye's (1938) patients gave no history of bathing in ponds, exposure to animals, or trauma. Ocular rhinosporidiosis, as it occurs in dry regions in the Middle Eastern countries, is believed to have been due to the dustborne pathogen. Dust storms were suggested as the possible vehicle although ocular disease has been recorded in wet regions as well (Moses et al. 1990).

From a case of vulval rhinosporidiosis in a woman and penile rhinosporidiosis in her male sexual partner, Symmers (1966) postulated a sexual mode of transmission; Palaniswamy and Bhandari (1983) and Sasidharan et al. (1987) found no evidence for such transmission.

There is no evidence that humans can acquire the disease from animals (Lasser and Smith 1976). Humans and animals probably acquire the pathogen from the common source of ground waters. From the similarity noted between *Ichthyosporidium* and *Rhinosporidium* spp. (Laveran and Pettit 1910), Allen and Dave (1936) surmised that *R. seeberi* might also be a parasite of fish and that animals and humans could acquire the pathogen from inland waters which harbor infected fish. Reddy and Lakshminarayana (1962) found no evidence for the existence of *R. seeberi* in inland fish.

There is evidence for trauma as a predisposing factor; Moses and Balachandran (1987) reported that in 19 cattle with rhinosporidiosis, all had nasal disease at the site of the passage through the nasal septum, of the guiding nose-rope. Trauma followed soon after by exposure to stagnant water, featured in a case of nasal rhinosporidiosis (Atav et al. 1955), and Symmers (1966) documented a case with trauma and simultaneous contact with stagnant water shortly preceding the appearance of the lesion at the traumatized site. The occurrence of rhinosporidiosis at a site of a closed injury that precluded exposure to soil, dust, or water, as with the rhinosporidial mass over the tibia (Figure 43, p. 31) could have resulted from bloodborne endospores which extravasated at the traumatized site. Trauma to the nose without exposure to soil or ground water, followed by nasal rhinosporidiosis, has also been reported (Weller and Riker 1930; Jimenez et al. 1984). Finger-borne inoculation in anterior nasal passages has been suggested (Forsyth 1924; Karunaratne 1964), although the development of lesions in the nasopharynx cannot be thus explained.

Penile and anterior urethral rhinosporidiosis in the male is thought to result from the application, by some communities in whom rhinosporidiosis in these sites is commoner, of a stone or piece of brick to absorb the last drops of urine (Kurup 1931; Kutty and Unni 1969).

Predisposition to infection

A history of bathing in ground waters is common in Sri Lankan patients. On the other hand, whilst numerous persons bathe in such waters, only a small proportion of these bathers acquire the disease, suggesting the existence of predisposing host factors. The only host factor that has been investigated is blood group; Kameswaran and Lakshmanan (1999) reported that in India, group O had the highest incidence (70 percent) in rhinosporidial patients followed by group AB, although groups A, B, and O are distributed 'fairly equally,' whilst group AB is rare. Jain (1967) found no association of incidence with blood groups. In our series of 21 Sri Lankan patients, the pattern differed: group O, 43 percent; group A, 29 percent; group B, 19 percent; and group AB, 10 percent; with a population distribution of 43 percent, 21 percent, 26 percent, and 5 percent, respectively. HLA or genetic typing of rhinosporidial patients would be of interest.

The possible existence of host factors that predispose to infection is suggested by the development of rhinosporidiosis in boys but not in girls who lived under the same conditions, using the same swimming baths (Karunaratne 1936).

CLINICAL FEATURES

Sites

The most common (70 percent) sites of solitary growths are the vestibule of the nose (Figure 32), the septum, and the inferior and middle turbinates and the floor of the nasal acvity. Bilateral (Figure 33) or multiple polyps are less common. Other respiratory sites are the adjacent sinuses, nasopharynx, fauces, soft palate, inner end of the Eustachian tube, tonsil and larynx, and occasionally the trachea and bronchi. Nonrespiratory sites with single or multiple polyps (10 percent) are the skin of the face (Figure 34), scalp, body (superficially, subfascially, or intramuscularly), external ear, vulva, vagina, rectum, glans and fossa navicularis of the penis, and the external urethral meatus of males and females. It is claimed (Kutty and Unni 1969) that in anterior urethral rhinosporidiosis in the male, infection is initiated by the rubbing of stones to absorb the last drops of urine by certain communities; the stone could cause abrasions in the epithelium while containing the soil or water-based pathogen,

Pulmonary lesions have been rare and rhinosporidiosis in the anterior buccal cavity has not been reported; this rarity is conceivably associated with continual flushing of the cavity with food and fluids, leaving insufficient contact time for implantation of the organism. Rhinoporidiosis has, however, occurred in the parotid gland

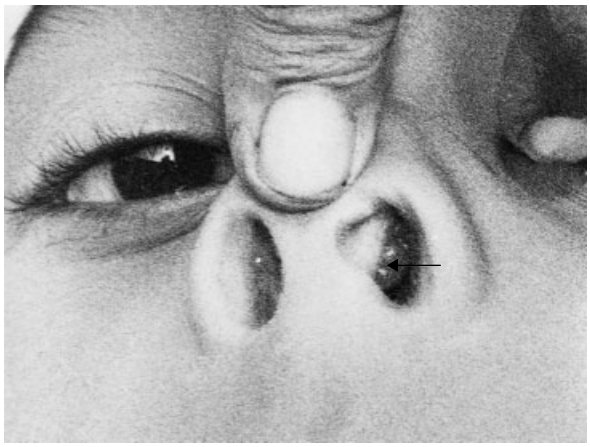

Figure 32 *Early, strawberry-like, pedunculated rhinosporidial polyp (arrow) in nasal vestibule. (Courtesy Dr P. Balasooriya, Sri Lanka)*

Figure 33 *Bilateral rhinosporidial masses obstructing anterior nares, in advanced disease. (Courtesy Dr P. Balasooriya, Sri Lanka)*

(Mahadevan 1952), a rare site, infection in which was thought to have arisen through the Stenson's duct from the oral cavitiy. Approximately 15 percent of all cases of rhinosporidiosis are in ocular sites (oculosporidiosis) with palpebral conjunctival lesions being the commonest (Figure 35). Ocular polyps are painless, granular, often sessile masses; they could occur in the limbus, canthus, and lacrimal duct and sac with spread to the nose (Kirkpatrick 1916). With involvement of the bulbar conjunctiva, scleral 'melting' and staphyloma formation are complications (Castellino et al. 2000). The lacrimal apparatus – lacrimal sac, nasolacrimal duct – could also be involved (Kameswaran 1966). Obstruction of the lacrimal duct may lead to suppurative dacryocystitis with secondary infection. The idea that the initial focus of infection is the lacrimal duct is probably invalid as nasal lesions have been on the contralateral side. Ocular cases have occurred predominantly in dusty regions rather than in wet agricultural areas, while also being preceded by injuries to the eye.

Sites in disseminated cases include the brain (Alessandrini 1926 quoted by Karunaratne 1964), bones of limbs

Figure 34 *Verrucous rhinosporidial polyps on the face of a man aged 41 years. (Courtesy Dr P. Balasooriya, Sri Lanka)*

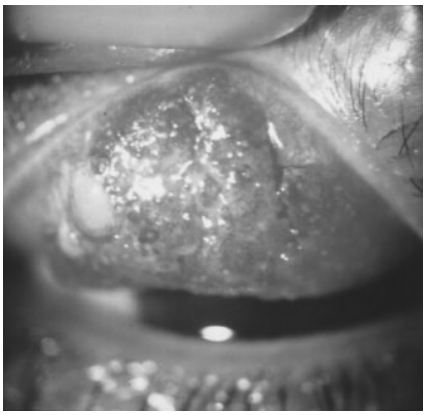

Figure 35 *Sessile rhinosporidial mass on upper palpebral conjunctiva, with a fluid-filled vesicle on outer surface of the eyelid. The vesicle disappeared after surgical excision of the rhinosporidial mass. (Courtesy Dr C.R. Seimon, Sri Lanka)*

(Nguyen-Van-Ut et al. 1959; Chatterjee et al. 1977; Aravindan et al. 1989; Gokhale et al. 1997; Figure 36), the skin, and the abdominal viscera.

Rhinosporidial polyps on nonrespiratory sites of the body, notably the skin and subcutaneous tissues, could occur without primary lesions in respiratory or ocular sites (Madhavan et al. 1978).

Symptoms

The presenting symptoms depend on the site of the disease. In respiratory sites, the commonest symptoms are obstruction to breathing, and bleeding even with minimal trauma of sneezing or nose-blowing. Changes in voice occur in laryngeal disease. Pain is uncommon.

PATHOLOGY

Macroscopic appearances

The macroscopic appearances vary with the site of rhinosporidial polyps. Nasal polyps are typically strawberry-like masses with pinhead-sized, cream-colored spots due to mature subepithelial sporangia. Polyps on the skin, and in respiratory sites, could be sessile or pedunculate and non-infiltrating into deeper tissues; this latter feature makes the radical excision of pedunculate polyps possible with minimal spillage of endospores and uncommon recurrence, while the excision of sessile polyps might be incomplete, with contamination of the adjacent mucosa by endospores leading to recurrence. Most polyps are lobulated and, in the nasopharynx, the lobes appear variegated with smooth, nongranular surfaces or granular and vascular in other areas; histopathological diagnosis is easier with the latter portions of the growth. Polyps with a verrucous surface might

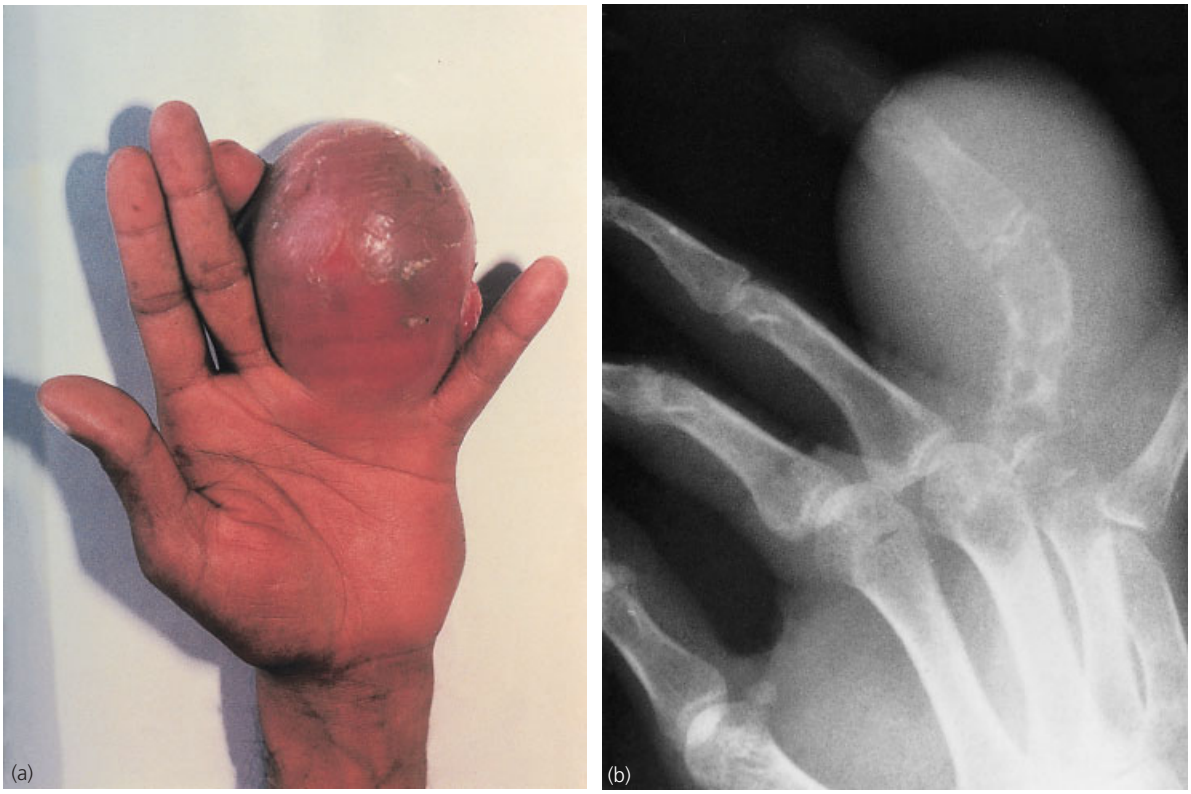

Figure 36 (a) *Globular rhinosporidial mass on finger, in a patient with disseminated rhinosporidiosis. (Courtesy Dr S. Gokhale, India).* **(b)** *Radiograph of fingers of patient in* **(a)**, *showing destruction and fracture of bones of the affected finger. (Courtesy Dr S. Gokhale, India)*

entrap other microorganisms from the aquatic habitat; this is of importance in sampling for purposes of culture in that contaminating microorganisms which appear in culture might be erroneously incriminated as the cause of rhinosporidiosis (see Krishnamoorthy et al. 1989; Ahluwalia et al. 1997; Ahluwalia 1999).

Polyps in respiratory sites are usually covered with mucus in which numerous endospores may be detected on stained smears. Growths on the skin of the body might undergo ulceration and de-epithelialization, and secondary infection, and then mimic malignant tumors. Pus formation is uncommon. Bones, as in the foot, hand or limbs, which underlie rhinosporidial masses, could show erosion or fractures on radiographs (Chatterjee et al. 1977; Gokhale et al. 1997; Figure 36b).

Disseminated rhinosporidiosis is relatively rare, and presents with masses of varying size on the face, trunk, limbs, and in the viscera including the liver, spleen, brain, and kidneys (Rajam et al. 1955; Agrawal et al. 1959). Rhinosporidial endospores and sporangia in these cases have been detected microscopically in the blood vessels. Lymph node enlargement, even in disseminated rhinosporidiosis, is curiously uncommon (Chatterjee et al. 1977), although it is possible that lymph nodes have not been examined in patients with disseminated disease.

Microscopic appearances

The histopathological pattern in human rhinosporidiosis shows wide variation, especially in the stroma and infiltrating cells (Arseculeratne et al. 2001). The various developmental stages of the organism can be seen in a single histological section (Figure 3) and their presence, rather than the host's tissue response, affords a definitive diagnosis.

The epithelium overlying mature sporangia is attenuated or hyperplastic with keratinization, and acanthotic with downgrowths that surround the sporangia (see Figure 19). This phenomenon is further discussed under Transepidermal elimination below. Proliferation of respiratory (ciliated, columnar) epithelium results in a papillary appearance, with many goblet cells and hypersecretion of mucus (Karunaratne 1964). Growths on the skin may be denuded of epithelium and ulcerated.

Endospores and sporangia (Figure 18) have been seen intraepithelially (Noronha 1933; Karunaratne 1964); it is uncertain whether the presence of sporangia, intraepithelially, results from the development of intraepithelial endospores after 'transepithelial infection' (Karunaratne 1964) or from transepidermal elimination (see below), with the organism being 'thrust into the epidermis from the subjacent connective tissue' (Ashworth 1923; Figures 37 and 38). Endospores

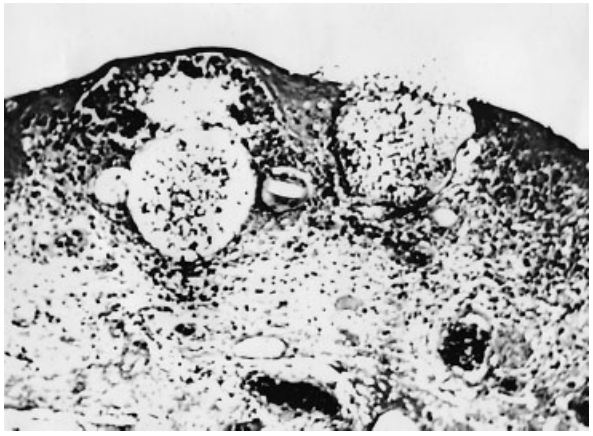

Figure 37 *Late stage of 'transepidermal elimination' of sporangia and endospores in ocular rhinosporidiosis. Note thinned epithelium. H&E; initial magnification ×400*

occur in both the mature sporangia as well as free, extrasporangially, in the tissues.

Fibromyxomatous or fibroedematous reactions occur in the subepithelial stroma with few or absent sporangia (Figure 39). Tirumurti (1914) noted myxomatous degeneration, especially in nasal polyps. Mild-to-moderate inflammatory cell infiltrates accumulate around a multitude of sporangia (Figure 40) and, more prominantly, around fee endospores. The cells include lymphocytes, plasma cells, histiocytes, neutrophils (especially around free endospores and with secondary infection), and rarely eosinophils; these are in varying proportions depending on the chronicity of the polyp. The paucity of eosinophils contrasts rhinosporidiosis with opportunistic, mycelial deep mycoses; there is also no eosinophilic precipitate (probably of antigen/immunoglobulin complexes) (Grover 1970), the Splendoré–Hoeppli phenomenon, seen around hyphae of *Entomorphthora coronata* (a cause of nasal polyps in horses) and *Basidiobolus ranarum*, and in other zygomycotic tissues (Williams 1969).

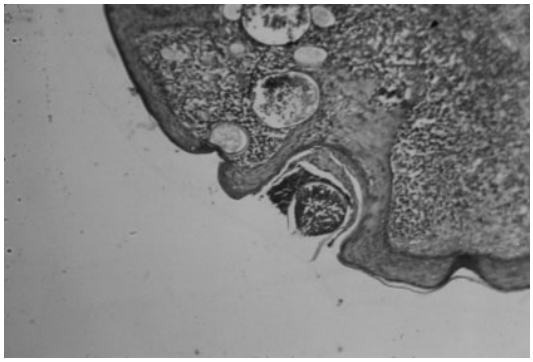

Figure 38 *Subcutaneous rhinosporidiosis with down-growth of squamous epithelium encircling a degenerate sporangium, illustrating 'transepidermal elimination' of degenerate sporangia. PAS stain; initial magnification ×200*

Figure 39 *Acanthotic squamous epithelium (a), fibromyxomatous stroma (f), with sparse cell infiltration in an area with scarce sporangia, in nasopharyngeal rhinosporidiosis. H&E; initial magnification ×400*

With secondary infection, neutrophils are numerous. Stromal microabscesses may occur (Jimenez et al. 1984). The predominant mononuclear cell in the stroma is the plasma cell (Kaye 1938). In more chronic lesions, lymphocytes and macrophages predominate. Invading connective tissue (Figure 22) or multinucleate giant cells (Figure 23) may be seen within degenerate or empty sporangia, which may also be calcified. Stromal giant cells occasionally contain juvenile sporangia (Karunaratne 1964). In a rare case of fatal, disseminated visceral rhinosporidiosis, Rajam et al. (1955) found relatively insignificant histopathology or evidence of inflammatory reactions around the sparse sporangia and endospores in the viscera.

Marked vascularity, resulting in focal hemorrhage in the polyp and severe external hemorrhage following surgery or trauma, occurs with the very vascular polyps, especially in nasal rhinosporidiosis (see Figure 19). Empty spaces (Figure 19) occur in the stroma and are derived from the destruction of tissue elements or from dilated glands or ducts in glandular tissues (Karunaratne 1936). They are commoner in nasal rhinosporidiosis (Beattie 1906). There is minimal fibrosis which is more marked in lesions that are regressing under dapsone therapy (Job et al. 1993).

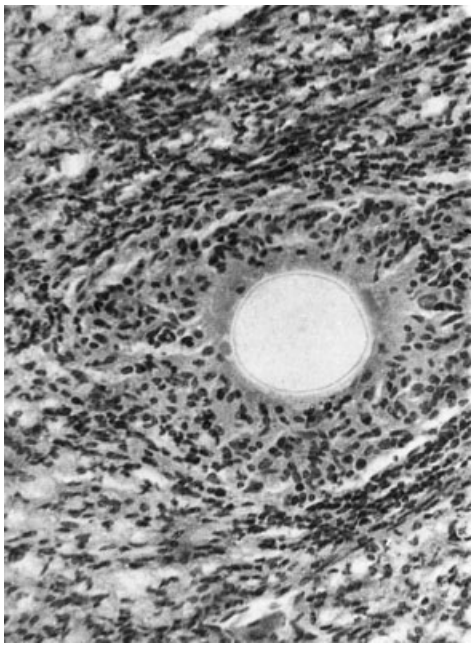

Figure 40 *Mononuclear cell infiltration around degenerate sporangium. H&E; initial magnification ×400*

Erosion of bone (Figure 36b) or cartilage with perforation of the nasal septum has been recorded (Atav et al. 1955; Chitravel et al. 1990; Gokhale et al. 1997).

TRANSEPIDERMAL (TRANSEPITHELIAL) ELIMINATION OF RHINOSPORIDIAL ENDOSPORES

This term was applied to the presence of rhinosporidial sporangia in subepithelial sites, with their endospores exiting through the breached epithelium (Figures 37 and 24.38). In only three reports (Thianprasit and Thagernpol 1989; Azadeh et al. 1994; Kennedy et al. 1995) has this term been used.

In what may be construed as the sequence of this process, the early stages of this phenomenon are characterized by the formation of downgrowths of the deeper layers of the epidermis to surround the mature dermal and subdermal sporangia (Figures 19 and 24.38). These downgrowths often appear histologically as 'whorls' (Arseculeratne et al. 2001; see Lever and Schaumberg-Lever 1990) and have also been described as a response to chemical irritants (Lever and Schaumberg-Lever 1990); their presence in rhinosporidial tissues is therefore not a specific reaction in this disease, and it might alternatively be regarded as a nonspecific defense reaction against irritants. This phenomenon was thought to represent a nonspecific defense mechanism of the host for the expulsion of rhinosporidial sporangia and endospores. Thinning of epithelium (Figure 37) which overlies the sporangia was thought to result from pressure from the underlying sporangia.

On a parallel with the amphibian skin pathogen *Batrachochytrium* (Daszak et al. 1999), it was postulated (Arseculeratne et al. 2001) that the phenomenon in rhinosporidiosis could, on the other hand, be the pathogen's mechanism for endospore dispersal. The apparent migration of the mature sporangia towards the surface of the epithelium could be due to the dissolution of the tissues by histolytic enzymes of *R. seeberi* rather than through a mere effect of pressure which forces the sporangium towards the epithelium. Broz and Privora (1952) described a similar appearance in the granulomatous lesions in frogs caused by *Dermocystidium*: 'When the cyst reaches the surface of the skin, it becomes exposed, owing to ulceration of the epithelium, and its membrane ruptures, setting the spores free.' *Dermocystidium* is now included with *Rhinosporidium* in the proposed Class Mesomycetozoea (Herr et al. 1999b). In Figure 2 of Wallin et al.'s (2001) paper on rhinosporidiosis in a cat, 'the ''nipple-like'' projection', of the mature sporangium projected into the nasal cavity; this appearance recalls that described by de Mello (1954) of the sporangial pore that is directed towards the surface of the epithelium.

The conceivable defensive role of the epithelium on the part of the host, together with the apparent migration of the sporangia towards the surface of the epithelium in the postulated pursuance of the release of the endospores on the part of the pathogen, constitute the phenomenon of 'transepidermal (epithelial) elimination' of sporangia and endospores.

MODE OF SPREAD

Rhinosporidial infection spreads locally, regionally, and to distant, anatomically unrelated sites.

From upper respiratory sites, especially the anterior nares where the disease most often begins, local and regional spread occurs in the nasal passages, extending to the nasopharynx, lacrimal apparatus, and paranasal sinuses; in these instances, the spread is probably through autoinoculation (Weller and Riker 1930; Karunaratne 1936) of adjacent sites by endospores released spontaneously from adjacent polyps or after surgery. In Ingram's case (1910), the initial growth in the external urethral meatus spread to involve the glans within a period of 2 years, thus spreading more slowly than in other sites. Dissemination refers to the occurrence of lesions in sites such as the limbs and viscera that are anatomically unrelated or distant from the initial foci in the upper respiratory passages.

Lymphatic spread has not been documented, although postulated (Ashworth 1923) in cutaneous and subcutaneous rhinosporidiosis (Agrawal et al. 1959; Agarwal 1966), although such spread will not explain dissemination to anatomically unrelated sites. None of the numerous reports on rhinosporidiosis has described the occurrence of lymphadenitis. de Mello (1954) stated that 'lymphatic nodes are not affected,' nor did Pumhirun et al. (1983) find enlarged lymph nodes in their case of nasopharyngeal and facial rhinosporidiosis. The presence

of enlarged inguinal and epitrochlear lymph nodes in a case of disseminated rhinosporidiosis was noted by Agrawal et al. (1959) though the histology of the nodes was not commented on. Neither Chatterjee et al. (1977) nor Agarwal (1966) who studied 27 cases, found enlargement of lymph nodes in their cases of disseminated disease.

Inguinal lymphadenitis was recently described (Arseculeratne et al. 2001) in a Sri Lankan patient with disseminated disease involving the lower limbs. The criteria on which lymph node involvement was made included the location of the mass in the site of inguinal lymph nodes, the histological presence of a capsule in the mass, trabeculae from the capsule towards the center of the mass, a subcapsular sinus, and masses of lymphocytes which probably represented the cortical follicles (Figure 41).

Lymphadenitis in rhinosporidiosis is apparently rare, contrasting with its frequency in systemic mycotic disease; this rarity might be based on mechanisms of immune evasion in rhinosporidiosis which are discussed below.

There is also histological evidence for hematogenous spread of rhinosporidiosis to anatomically distant sites; Rajam et al. (1955) identified endospores and sporangia in the lumen of renal blood vessels, urine, ascitic fluid, and viscera; these authors' case is of interest in that growths were not found in the nose, nasopharynx, or urethra, which are common initial sites of rhinosporidiosis. Sporangia with endospores were also found within blood vessels in the case of Ho and Tay (1986). Figure 34 illustrates facial polyps in a Sri Lankan patient that developed a few years after excision of a nasal polyp; amongst 20 other rhinosporidial masses on the rest of this patient's body was a pedunculated mass on the chest wall (Figure 42) and a large subcutaneous mass that appeared at the site of a previous closed injury on the leg (Figure 43). Hematogenous spread to these sites could have followed the nasal infection.

Concurrent diseases

Infections or malignancies concurrent with rhinosporidiosis, in the same or different sites or adjacent tissues, have been recorded; in conjunctival rhinosporidiosis with papillomavirus (Noor-Sunba and al-Ali 1989); papovavirus infection (Noor-Sunba et al. 1988); squamous carcinoma of the tongue (Karunaratne 1936), Ahluwalia and Bahadur 1990); leprosy with nasal (Allen and Dave 1936; Rosenbaum and Gan 1948) and cutaneous rhinosporidiosis (Porichha et al. 1986; Jayakumar et al. 1995); syphilis (Satyanarayana 1960); rhinoscleroma (Al-Serhani et al. 1998) in humans; and schistosomiasis in bovines (Rao 1938). Rhinosporidiosis coexisted in 50 percent of bullocks with schistosomiasis of the nose (Datta 1965). Jain (1967) quoted Patnaik that rhinosporidiosis was not coexistent with schistosomiasis; in Sri Lanka, bovine nasal scrapings, from abattoir samples, showed schistosomes in approximately 75 percent of buffaloes and in 40 percent of cattle, while none had concomitant rhinosporidial endospores (Arseculeratne and Rajapakse 2001, unpublished data).

It is not clear whether the concurrence of these diseases with rhinosporidiosis has a causal, sequential, or coincidental basis. In view of the occurrence of suppressor immune reactions in rhinosporidiosis, discussed under Immunity below, local or generalized cell-mediated immunity (CMI) anergy might occur with some of these associated diseases. In cats, rhinosporidiosis was not associated with the feline leukemia and feline immunodeficiency viruses (Wallin et al. 2001). There is no evidence in the voluminous literature that rhinosporidiosis is an opportunistic infection, although Stricker et al. (1999) reported a case of a human immunodeficiency virus (HIV)-positive man who had an unusual infection which these authors claimed to be rhinosporidiosis; their histopathological section photograph, however, does not reveal the different stages of *R. seeberi*'s development which are invariably seen in rhinosporidial tissue (Figure 3). In the extensive literature on clinical rhinosporidiosis, from diverse environments, such an association between an identified immunodeficient state and rhinosporidiosis has not been recorded.

IMMUNITY

Information on mechanisms of nonspecific and specific adaptive antirhinosporidial immunity would be necessary to explain some predominant clinical characteristics of the disease – chronicity, spontaneous regression, recurrence after surgery, and occasional dissemination. Such data on mechanisms of antirhinosporidial immunity were scarce until recently, undoubtedly due to the absence of a method for obtaining pure preparations of *R. seeberi*, uncontaminated by host tissue and other microorganisms, and consequently the lack of reagents for suitable immunological tests in diseased hosts as well as in vitro. A further lack was an experimental model of rhinosporidiosis.

Only one report is available on mechanisms of antirhinosporidial humoral immunity (Chitravel et al. 1982) that described the use of crude preparations of endospores and sporangia obtained from human polyps. Homogenates after filtration and centrifugation were used with Freund's complete adjuvant as antigens for the preparation of antirhinosporidial antibodies. These authors were not able to demonstrate antirhinosporidial antibody in patients by double diffusion tests in gels or counterimmunoelectrophoresis (CIE), but reported that rhinosporidial antigen(s) were detected in rhinosporidial patients' sera by gel diffusion tests. Kwon-Chung and Bennett (1992) pointed out that Chitravel's gel precipitin lines could have been due to human antigens that contaminated the crude rhinosporidial antigen preparations and which reacted with antihuman antibody from the experimental animals that were immunized with the crude antigen preparations. If these preparations did not contain mature sporangia, then new rhinosporidial antigens which appear only in maturing sporangia (Herr et al. 1999c), might also have been excluded. Crude preparations of endospores and sporangia were also used by Reddy and Lakshminarayana (1962) in agglutination tests, which, however, gave inconclusive results, as agglutination was caused by sera from normal humans as well as from patients with rhinosporidiosis.

New information on cell-mediated and humoral antirhinosporidial immunity in human rhinosporidial patients and in experimental mice is now available and is reviewed below.

Cell-mediated immune responses

Cell-mediated immune responses (CMI) in rhinosporidiosis was investigated by Reddy and Lakshminarayana (1962) by the 'cutaneous' injection of crude preparations of rhinosporidial endospores. Transient erythematous reactions were produced in normal persons as well as in rhinosporidial patients, and these authors concluded that these reactions were nonspecific.

The only definitive report on cell-mediated immunity in rhinosporidial patients was that of Chitravel et al.

(1981); they used the Leukocyte Migration Inhibition (LMI) test and found that, in patients with disease of less than 9 years' duration, LMI was detectable but that the inhibition decreased when the disease was of longer duration. These authors suggested that immunological 'unresponsiveness or tolerance' might explain this finding. Our data on antirhinosporidial CMIR in mice, discussed below, elucidates Chitravel's results.

CMI responses in human rhinosporidiosis were recently described (de Silva et al. 2001). Two approaches were used:

1. immunohistochemistry with monoclonal antibodies against specific markers on cells in human rhinosporidial tissues
2. in vitro lymphoproliferative responses (LPR) of peripheral blood lymphocytes from rhinosporidial patients to the T-cell mitogen concanavalin A (conA) and to sonic extracts from Percoll-purified rhinosporidial endospores and sporangia.

The cell infiltrate in human rhinosporidial polyps showed similar patterns despite their origin from different clinical presentations and of differing durations. In composition, the infiltrates were mixed; neutrophils were abundant, CD20+ B cells were present in considerable numbers with plasma cells, CD68+ macrophages (Figure 44), some of which were foamy, and CD3+ T lymphocytes, were numerous. CD4+ helper T lymphocytes were scarce, while the presence of CD8+ T-cytotoxic/suppressor lymphocytes was marked; CD8+ cytotoxic/suppressor T lymphocytes were found specially around and within mature sporangia (Figure 45).

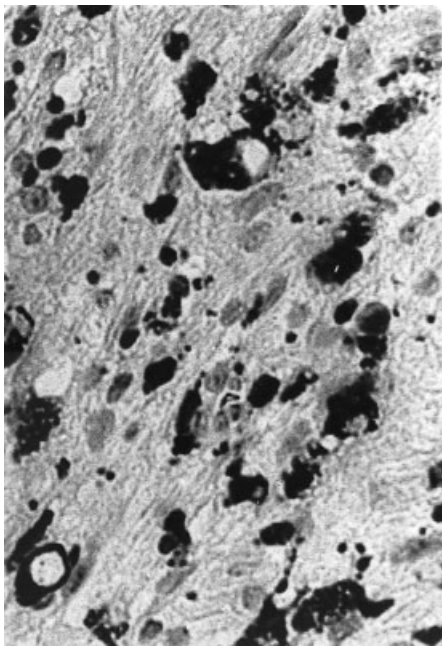

Figure 44 *CD68+ macrophages in rhinosporidial stroma, visualized with monoclonal antibodies-Dako Fast-red. (Reproduced with permission from* Mycopathologia*, 2001;***52***: 59–68)*

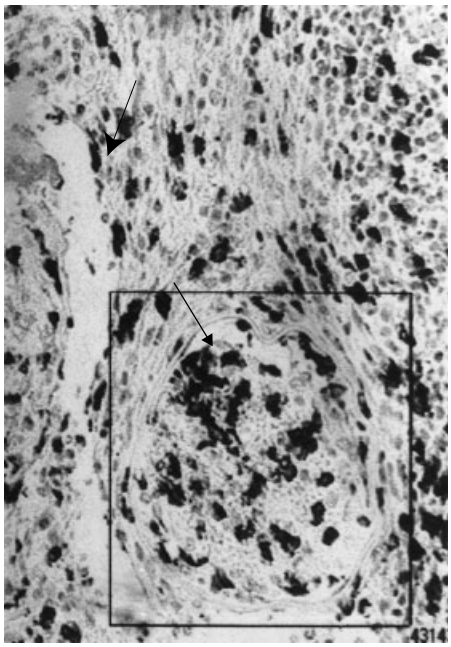

Figure 45 *CD8+ T lymphocytes in rhinosporidial stroma and within a mature, degenerate sporangium (arrow), visualized with monoclonal antibodies-Dako Fast-red. (Reproduced with permission from* Mycopathologia*, 2001;***52***:59–68)*

There were many TIA1-positive lymphocytes of the cytotoxic subtype located especially around the sporangia. CD56/57+ NK lymphocytes were less numerous than CD8+ T lymphocytes and were also located around mature sporangia.

In LPR assays in vitro (de Silva et al. 2001), rhinosporidial lymphocytes showed stimulatory responses (stimulation indices (SI) >1, Figure 46) with conA, but the majority of these samples showed significantly diminished responses to rhinosporidial antigens, indicating that suppressor responses could occur in human rhinosporidiosis. The SI of lymphocytes from control (nonrhinosporidial) persons and the SI of lymphocytes from rhinosporidial patients, to conA showed no significant differences, indicating that the rhinosporidial patients had general adequate cell-mediated immune competence. There was, however, no correlation between the intensity of the depression of the LPR-SI to rhinosporidial antigen and the site, duration of the disease, the number of lesions, or to the presence of dissemination. These results demonstrate that while on the one hand a CMIR does develop in human rhinosporidiosis, suppressor responses, on the other hand, also occur.

In some patients, the peripheral blood lymphocytes showed a significantly lower proliferative response to rhinosporidial antigen than to conA, suggesting that the suppression was antigen-specific; the rhinosporidial antigen did not suppress the response to conA when the two agents were mixed, nor was the antigen toxic to the lymphocytes.

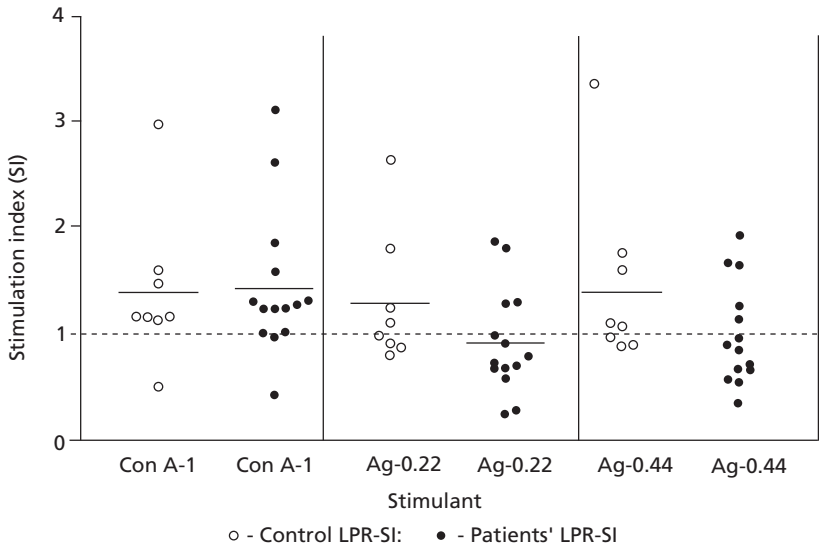

Figure 46 *Scatter of LPR-SI of control subjects and rhinosporidial patients to conA and rhinosporidial extract (RhA) as stimulants. Horizontal bars represent mean values. Open circles, control LPR-SI; filled circles, patients' LPR-SI. (Reproduced with permission from* Mycopathologia, *2001;***52***:59–68)*

The delayed-type hypersensitivity (DTH) Mantoux reactivity to PPD-S from *Mycobacterium tuberculosis* was markedly depressed (to approximately 25 percent) in most Sri Lankan patients with rhinosporidiosis (with or without prior bacille Calmette–Guérin (BCG) vaccination), although the Mantoux reactivity was far more pronounced in normal and BCG-vaccinated populations (75 percent); no correlation was found between Mantoux-negativity and the clinical state of rhinosporidiosis – whether respiratory or in other sites, localized or disseminated, or with single or multiple polyps – as with the lymphoproliferative responses in vitro (de Silva et al. 2001). Rhinosporidial antigen prepared from purified, sonicated endospores and sporangia from the polyps of one patient with disseminated disease, injected intradermally in the same patient, gave a negative skin reaction, correlating with the significantly depressed lymphoproliferative response (SI < 1) in this patient.

The CMI anergy demonstrated in rhinosporidial patients and in in vitro tests needs further study for the determination of whether the suppression is a result of general, nonspecific suppression of CMI or is antigen-specific.

CMI responses in experimental animals have hitherto not been examined. CMIR to *R. seeberi* in experimental mice were recently studied by the quantitative footpad response of the DTH, with histopathology of the treated footpads for confirmation of the DTH-type response. Jayasekera et al. (2001) demonstrated that sonicated suspensions of rhinosporidial endospores and sporangia, used for sensitization and challenge, evoked well-marked DTH-type footpad responses of a magnitude similar to that evoked by T-dependent antigens such as sheep red blood cells. The footpads challenged with rhinosporidial extracts showed histopathology (Figure 47) which was typical of DTH reactions in the mouse.

An interesting finding in the mouse experiments was that, in comparison with the results after a single sensitizing dose of rhinosporidial antigen(s), repeated sensitization resulted in the decrease in the intensity of the DTH footpad response; conversely, the humoral immune response was significantly elevated. This phenomenon of immune deviation has been ascribed (Mosmann and Sad

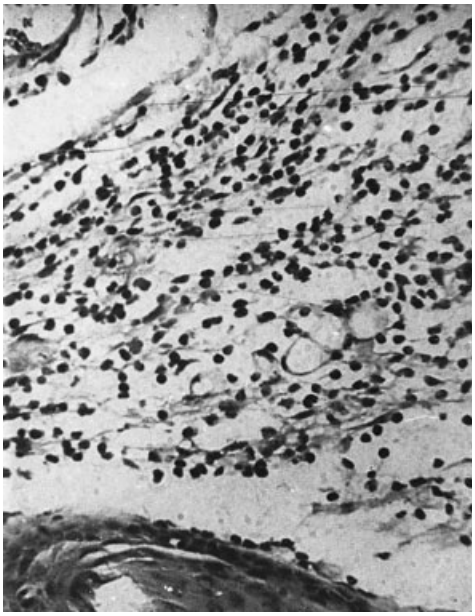

Figure 47 *Footpad of mouse showing DTH reaction to challenge following sensitization with extract of rhinosporidial endospores/sporangia, with infiltrate of neutrophils, macrophages and lymphocytes. H&E; initial magnification ×400*

1996) to the switch, on repeated administration of antigens, from activation of CD4+ Th0 cells to the production of CD4+ Th2 cells which encourage antibody production, after an initial production of CD4+ Th1 cells which induce DTH. The ensuing decrease of DTH reactivity with the switch from Th1 to Th2 might contribute to decreased antirhinosporidial cell-mediated immunity and might explain the chronicity, recurrence, and dissemination in clinical rhinosporidiosis. This finding might also explain Chitravel et al.'s observation (1981), that the intensity of LMI waned when the duration of the disease was greater than 9 years.

Humoral immune responses

Jain (1967) used a suspension of 'spores' as antigen, injected subcutaneously in humans, and concluded that '... this disease does not produce any sensitizing antibodies' as no reactions were produced in either one hour or after 3 days.

Reddy and Lakshminarayana (1962) used suspensions of endospores and sporangia from homogenized rhinosporidial tissues, in agglutination tests for experimental antirhinosporidial antibody and observed nonspecific 'clumping.' The same antigen was used in 'cutaneous' tests on patients and normal persons, but no specific reactions were detected.

Chitravel et al. (1982) reported that antirhinosporidial antibody was not detected in patients by immunodiffusion or CIE; they used suspensions of endospores and sporangia, that were ground with glass powder. Precipitin lines were, however, detected in our (Arseculeratne et al. 1999) CIE tests with antigens released by ultrasonic disintegration of Percoll-purified endospores/sporangia, and human rhinosporidial sera, and the possibility remains that Chitravel's antigen preparations had insufficient amounts of soluble antigen. Antirhinosporidial humoral immune responses (HIR) was also detected in experimental mice (Jayasekera et al. 2001) and rabbits (Atapattu et al. 1999) by indirect immunofluorescence tests which used Percoll-purified, sonically disrupted endospores and sporangia as antigen. Rhinosporidial patients' sera, tested by indirect immunofluorescence, had appreciable titers (over 1/320) whereas only two of 30 clinically nonrhinosporidial persons showed low (1/30) titers; these two persons were from an area endemic for rhinosporidiosis and might have been subclinically exposed to the organism with consequent immunization. Antibody titers of over 1/320, especially of IgG and IgM, were also detected in patients' sera in immunodot blot assays on nitrocellulose paper, with specific antihuman immunoglobulin phosphatase-conjugated tracers (Arseculeratne et al. 1999 and unpublished data 2002).

It can be concluded that *R. seeberi* shows a variety of mechanisms of evasion of immune responses, which might explain some hitherto enigmatic aspects of rhinosporidiosis, viz. chronicity, recurrence, and dissemination:

- antigenic variation, based on the findings of Herr et al. (1999c)
- immune suppression as demonstrated by de Silva et al. (2001)
- immune distraction: the cell-infiltration patterns in rhinosporidial tissues in some cases indicate that infiltrates occur in some areas of the tissue in which rhinosporidial bodies are absent, suggesting that the infiltrates were in response to free rhinosporidial antigen. If this were the case, the possibility of immune distraction by free antigen in 'mopping up' of antirhinosporidial antibody might conceivably contribute to immune evasion by *R. seeberi* (Arseculeratne et al. 2001)
- immune deviation: experimental studies on CMIR in mice to *R. seeberi* (Jayasekera et al. 2001) suggest the occurrence of immune deviation which might further contribute to immune evasion through decreasing antirhinosporidial CMI reactivity, if, indeed, antirhinosporidial CMIR is protective
- binding of host immunoglobulins (Atapattu et al. 2000)
- antigen sequestration: the thick wall of the endospores which contains chitin and cellulose is conceivably impermeable to release of antigens or to immune destruction of the endospores, as perhaps with encysted parasites (Abbas et al. 2000). Selective permeability, however, to smaller molecules probably exists in rhinosporidial endospores, as shown by the entry of Evan's blue and MTT into endospores as described above. Moreover, the endospore of *R. seeberi* is not comparable with the encysted resting stage of amebae but is a vegetative stage in its life cycle.

It is interesting that several of these mechanisms of evasion of immune responses have also been described in parasitic infections, notably malaria (Goonewardene et al. 1990; see also Kierszenbaum 1994) and in fungal infections (chromomycosis, Fuchs and Pecher 1992; see also Cuff et al. 1986 on *Candida albicans*).

DIAGNOSIS

Urgency in diagnosis of rhinosporidiosis arises from its mimicry of malignant tumors (Figure 43).

Clinical clues to diagnosis

The macroscopic features of polyps and the clinical presentation, especially of nasal polyps, facilitate diagnosis. Rhinosporidiosis presents as single, or less frequently multiple, polyps in respiratory or ocular sites. The polyps are strawberry-like, red due to vascularity, with a granular surface that has yellowish, pinhead-sized spots. The polyps are friable and fragile, very vascular,

and bleed easily on handling. Lobulation, especially in nasopharyngeal sites, is common. Growths on the skin are often multiple and wart-like.

Differential diagnosis varies with the site. Urethral rhinosporidiosis needs differentiation from caruncles; nasal rhinosporidiosis from hypertrophic rhinitis, allergic polyps, vascular polyps, angiomas and fibromas, carcinoma (Ravi et al. 1992; Lourenco and Costa 1996), granulomatous leishmaniasis, leprosy, rhinoscleroma, and mycotic granulomas. Rhinosporidial lesions on the skin of the body may simulate viral warts, sarcomas, and leprous, tuberculous, or cryptococcal nodules.

Disseminated rhinosporidiosis is not uncommon. A history of nasal polyps and their surgical excision is often given, and the disseminated lesions appear several months or even years after the primary lesions. Growths of diverse appearances – pedunculated or sessile polyps or masses – appear on the body, face, scalp, limbs, and in the viscera (lungs, kidneys, liver, spleen, and brain). Rhinosporidial masses are accompanied by osteolysis and fractures of underlying bones (Figure 36b; Gokhale et al. 1997). Lymphadenitis, though hitherto unreported in rhinosporidiosis, was detected in a case of disseminated rhinosporidiosis in Sri Lanka as described above.

The contents of closed, subcutaneous lumps need microscopic examination of needle aspirates. The surface of mucosal polyps is often coated with mucus that contains numerous endospores which afford a convenient method for cytodiagnosis with PAS or silver-stained smears.

DIFFERENTIAL DIAGNOSIS

Rhinosporidiosis mimics, macroscopically, several infective and noninfective diseases. Noninfective diseases include:

- in the rectum: hemorrhoids and polyps
- in the nasal passages: papillary adenocarcinoma, hypertrophic rhinitis, beningn polyps
- in the eye: pterygia, mucocele of the lacrimal sac
- penile and urethral sites: squamous carcinoma, condylomata
- on the body: sarcoma, verruca vulgaris, fibroma, angiofibroma.

Infective diseases include rhinoscleroma, cryptococcosis, chromo(blasto)mycosis, histoplasmosis, infections caused by *Chrysosporium (Emmonsia) parvum* vars. *parvum* and *crescens*, blastomycosis, and paracoccidiodomycosis. The agents of these diseases have distinguishing morphological and tinctorial features and may also be cultured in vitro and in experimental animals, especially mice.

HISTOPATHOLOGY

The definitive diagnosis of rhinosporidiosis is by histopathology on biopsied or resected tissues. A histopathological diagnosis is based on the classical descriptions of rhinosporidial pathology, of Beattie (1906), Tirumurti (1914), Ashworth (1923), and Karunaratne (1964). Most histological sections contain the different developmental stages of the pathogen (Figure 4), and these appearances are more specific than the tissue responses – stromal or cell infiltrates – of the host; useful stains are H&E, PAS, mucicarmine, and Gomori's methenamine silver.

Autofluorescence of the sporangia and endospores, in sections of paraffin-embedded tissues, has been noted (Senba and Yamashita 1985; Moses et al. 1991) and merits consideration in tests that involve the use of fluorescent tracers.

Notable features of rhinosporidial histopathology include variations in the host responses:

- within the same specimen
- in different sites of the same and in different hosts, in respect of the density of the developmental stages
- in the stromal and cellular response (Arseculeratne et al. 2001).

Well-marked cell infiltrates, especially of macrophages and lymphocytes, occur around both intact, apparently viable sporangia that contain intact endospores as well as around degenerate, empty sporangia. Cell infiltrates could also be sparse around degenerate or intact sporangia in other regions of the same tissue and in samples from different patients. Kennedy et al. (1995) described similar histopathological variations in rhinosporidial tissues from swans; three patterns were identified:

- a severe, focal or diffuse acute and chronic inflammatory cell infiltrate
- granulomatous inflammation with epithelioid histiocytes and foreign body-type giant cells
- a fibroblastic reaction with paucity of sporangia and an inflammatory cell infiltrate, that was infrequent.

Rhinosporidial endospores and sporangia in disseminated cases involving the kidneys and liver might not be associated with a surrounding inflammatory cell infiltrate, although these bodies in the lung and subcutaneous tissues were found to have been surrounded by well-marked cell infiltrates (Agrawal et al. 1959).

Problems in histopathological diagnosis

Despite the ease of histopathological diagnosis through the ubiquitous developmental stages of *R. seeberi* in most rhinosporidial tissue, there are, however, problematic instances from which arise confusion, misdiagnosis, or a false-negative diagnosis. These instances which were described elsewhere (Arseculeratne et al. 2001) consisted of:

- rhinosporidial tissue in which rhinosporidial bodies were absent despite the presence of marked cell

infiltrates while other, more vascular, portions of the polyp, however, had rhinosporidial bodies; this problem occurs especially in the variegated polyps of nasopharyngeal rhinosporidiosis. Selection of typical portions of such polyps for histology might minimize the occurrence of a false-negative diagnosis
- atypical sporangia in which the well-marked, thick wall was absent
- the presence of only fragments of the sporangial wall, while endospores might or might not be present
- the absence of typical rhinosporidial bodies although PAS-positive bodies which are similar to the rhinosporidial endospores might be present indicating incipient or slow-growing rhinosporidiosis.

A noteworthy feature in rhinosporidial histopathology is the absence of the Splendoré–Hoeppli (antibody-mediated) reaction around rhinosporidial bodies. This reaction is often present in (mycelial) mycotic and some bacterial infections. This absence is remarkable in that rhinosporidial patients show high titers of anti-rhinosporidial antibody.

Differential histopathological diagnosis

A problem in differential histopathological diagnosis is that of subcutaneous spherulocystic disease (myospherulosis). Hutt et al. (1971) described it as 'reminiscent of an endosporulating fungus such as rhinosporidiosis;' McClatchie and Bremner (1969) noted it as a 'distant cousin of rhinosporidiosis.' The cysts of myospherulosis remain unstained with Gomori methenamine silver or with mucicarmine and no spores are present inside the cysts. The bodies in myospherulosis were regarded as erythrocytes, altered by exogenous or endogenous fat or lipids, or as derived from malignant cells or macrophages (Chau et al. 2000, see also Ali et al. 2001).

Histopathological differential diagnosis might also consider coccidiodomycosis in which *C. immitis* has mature stages which consist of large, thick-walled bodies which are smaller than the sporangia of *R. seeberi*, but which also contain endospores which are also smaller than those of *R. seeberi* and do not contain EDB.

CYTODIAGNOSIS

Cytodiagnosis is a useful method in diagnosis on aspirates from nonulcerated lumps in extrarespiratory sites (Kamal et al. 1995; Kavishkar et al. 1998), smears of the endospore-laden mucoid covering on the surfaces of polyps in the respiratory passages and from ulcerated polyps elsewhere in the body, washings of sinuses and bronchi, bronchial brushings, or fine-needle aspirates from bones (Pai et al. 1996). With suitable stains such as Gomori methenamine-silver, Papanicolaou's, PAS, Mayer's mucicarmine, and other stains, diagnostic features, especially of the endospores with their unique EDBs, are revealed (Ashworth 1923; Allen and Dave 1936; Kaye 1938; de Mello 1954; Rajam et al. 1955; Thomas et al. 1956; Vanbreuseghem 1958; Khan et al. 1969; Fortin and Meisels 1974; Chaudary et al. 1986; Jaiswal et al. 1992; Van der Coer et al. 1992; Gori and Scasso 1994; Maru et al. 1999). Wet mounts of the mucoid material on rhinosporidial polyps would also show the endospores with their EDBs (Figure 10).

In posterior respiratory sites, respiratory (columnar, ciliated) epithelial cells with their large nuclei could mimic endospores with the 'tail of the comet' appearance that is caused by the residue of the intrasporangia, mucoid material; caution was advised (Arseculeratne 2000a) in the identification of endospores in these sites (Figure 9). The PAS stain is particularly useful in this differentiation; the epithelial cell's nucleus is PAS-negative whereas the endospore stains markedly magenta.

Allen and Dave (1936) used nasal smears for monitoring antirhinosporidial chemotherapy, although it is noteworthy that the presence of endospores in nasal smears did not always correlate with the presence of nasal growths; smears from nasal passages after resection of the polyps have shown endospores with subsequent recurrence of the growth.

TREATMENT

Spontaneous regression of rhinosporidial polyps has been noted in humans (Forsyth 1924; Allen and Dave 1936; Karunaratne 1964; Anand et al. 1975) and in swans (Kennedy et al. 1995); it is rare, and surgical excision of the polyp, in accessible sites, remains the mainstay of treatment. Cauterization of the base of the excised polyp, especially in sessile growths, is recommended (Desmond 1953; Samaddar and Sen 1990; Ravi et al. 1992) to prevent, or at least minimize, recurrence. Excision with a snare was considered to result in dissemination and recurrence (Khan et al. 1969). Spillage of endospores by mere handling of the polyp or from its cut surface is probably responsible for the recurrence or development of new lesions on adjacent sites; this process was termed 'autoinoculation' (Karunaratne 1964). Satyanarayana (1960) esimated the recurrence rate after surgery at 11 percent, whilst Sasidharan et al. (1987) reported a recurrence rate of 25 percent in penile rhinosporidiosis.

Cryosurgery has also been used. Extensive growths have necessitated amputation, of the penis in disease of the glans, or of the foot or hand. Since rhinosporidial polyps in respiratory sites are very vascular, extensive hemorrhage needs caution (Khan et al. 1969).

Numerous antimicrobial agents – antimony compounds, bismuth, iodine, and pentamidine (Rajam et al. 1955), antifungal agents griseofulvin, amphotericin B, and topical steroids (Jimenez et al. 1984; Ho and Tay 1986), 5-fluorocytosine, potassium iodide, ketoconazole), quinine hydrochloride (Wright 1922), paludrine, pentamidine, antibacterial antibiotics, and deep x-ray therapy

(Satyanarayana 1960) – have not been demonstrated to have any effect. Trivalent or pentavalent compounds of antimony have been reported to have been of some effect and Wright (1922) claimed that ocular rhinosporidiosis responded to 2 percent tartar emetic (antimony potassium tartrate). Allen and Dave (1936) found 'neostibosan' to have been effective, with the disappearance of endospores from nasal secretions. Dapsone is the only drug that has been found, on clinical and microscopic grounds, to have a proven beneficial effect; it minimized recurrence and produced firmer, more fibrous, and less vascular nasal and nasopharyngeal polyps (Nair 1979); recurrence occurred in 28.6 percent of dapsone-treated patients whereas 93 percent of untreated patients required surgery for recurrent disease after a 3-year period. Histologically and ultrastructurally, it caused the arrest of the maturation of the sporangia and promotion of a granulomatous response with fibrosis (Job et al. 1993, see also Krishnan 1979; Venkateswaran et al. 1997). Its therapeutic role is, essentially, as an adjunct to surgery.

Failure of drug therapy was attributed to the impenetrability of the sporangial wall (Woodard and Hudson 1984).

RHINOSPORIDIOSIS IN ANIMALS

Several domesticated species [dogs (Easley et al. 1986), cats (Moisan and Baker 2001; Wallin et al. 2001), parrots], farm species [bovines (buffaloes and cattle), goats (Jain 1967), horses, mules, ducks, geese, swans (Kennedy et al. 1995)], and wild animals [the river dolphin *Inia geoffrensis* (Lipscomb 1998)], and water fowl have shown natural rhinosporidiosis. The only epizootic, of ocular and nasal rhinosporidiosis, occurred in swans (Kennedy et al. 1995). Nasal disease is more common in mammals. Rhinosporidiosis in animals is comparable with the disease in humans in many respects (Karunaratne 1964):

- predominance in males
- occurrence in India, South America, and South Africa
- general characteristics of the growths
- histopathological patterns and their variations.

In swans, Kennedy et al. (1995) described the epithelium as attenuated or acanthotic. The degree of acute or chronic inflammation was mild to moderate and showed three patterns:

1. a severe, focal to diffuse, acute and chronic cell infiltrate
2. a granulomatous reaction with epithelioid histiocytes and foreign body-type multinucleate giant cells commonly found centered around ruptured or collapsed, crescent-shaped sporangia
3. the least common pattern with fibroblasts usually associated with a paucity of sporangia and inflammatory cells.

These patterns are similar to those in human, equine (Rippon 1988), and canine (Easley et al. 1986) rhinosporidiosis.

There are no data on immunological responses in naturally occurring rhinosporidiosis in animals.

Ecology	2	Treatment	19
Epidemiology	5	References	19
Mycology	7		

ETIOLOGIC AGENT

Blastomyces dermatitidis is the etiologic agent of blastomycosis. This thermally dimorphic, presumably terricolous, fungus causes a primary acute or chronic infection of the respiratory system. In many instances the disease manifests itself as cutaneous lesions, but the fungus may infect almost any organ. *B. dermatitidis* exists in a yeast-like form in tissues or when incubated at 37°C. In nature or when incubated at 25°C on Sabouraud's glucose agar (SGA), it appears as a white, cottony mold. A definitive identification is made by the isolation of the etiologic agent. Prompt diagnosis requires a knowledgable physician and an astute microbiologist.

HISTORY

In 1894, Gilchrist, Assistant Dermatologist at Johns Hopkins Hospital in Baltimore, MD, presented a preliminary report on the first patient with blastomycosis (Gilchrist 1894). Formalinized tissue from the patient was referred to him as a case of scrofuloderma (cutaneous tuberculosis). The clinical appearance, according to the referring physician, was classic for this disease. The cutaneous manifestations of tuberculosis were common at that time and justified the diagnosis. Gilchrist examined the tissue histologically but was unable to find tubercle bacilli. However, he described the 'numerous curious bodies' that he saw in the excised tissue. Gilchrist called this disease process a protozoan dermatitis but expressed the opinion that the organisms were more probably of plant origin.

By the time he published an extended report on this patient he was convinced that the causative agent was a 'blastomycete,' a general term used at that time to refer to the yeasts (Gilchrist 1896). The histopathological description was thorough and complete. The illustrations in that paper demonstrate all the classic characteristics of this organism; the thick-walled, budding yeast-like cells with a broad base are clearly shown.

In his second report, also published in 1896, Gilchrist, with his colleague Stokes, described the remaining salient features of blastomycosis in another patient (Gilchrist and Stokes 1896). As these physicians had the opportunity to see this second patient, tissue specimens were taken for culture as well as histopathology. The typical unicellular tissue-form cells of *B. dermatitidis* were again described together with a complete histopathological account. The cultures from the diseased tissue grew in both their yeast and mycelial forms. Their observation of hyphae with distal and lateral cells or conidia on the mycelium led them to conclude that this agent was a filamentous fungus and not a true yeast.

The authors also observed that the mycelial form was not seen in tissues. They were inclined to separate *B. dermatitidis* from the other pathogenic 'blastomycetes' which later came to be known as species of *Candida* and *Cryptococcus*. As part of the investigation, they inoculated a dog intravenously with a pure culture of the patient's isolate. From the postmortem examination of this dog, they observed and reported on the

gross and microscopic features of bilateral pulmonary blastomycosis.

Extended observations of the isolate from the second patient were published in 1898 (Gilchrist and Stokes 1898). They detailed the budding mechanism, the various tissue stains which aided in the visualization of the organism, and the inflammatory reaction in the tissue. Extensive experiments with the isolate were also performed. They described the septations in the hyphae, observing the morphological variations of the yeast-like cells and mycelium, but did not recognize the thermal cause for the two forms. The isolates were found to be relatively inert biochemically.

In the early 1900s, both pulmonary and cutaneous blastomycosis were frequently misdiagnosed as manifestations of tuberculosis. At that time mycobacterial infections were more prevalent in the general population and there was considerably more medical knowledge of tuberculosis and its etiologic agent. Those clinicians who became familiar with blastomycosis were able to make the correct diagnosis.

During the next 10 years, many case reports of blastomycosis appeared in the literature. Ricketts, later of Rocky Mountain spotted fever fame, published an extensive review of blastomycosis in 1901 (Ricketts 1901). He reviewed the subtle differences between the blastomycetic diseases which were then known: cryptococcosis (*Cryptococcus neoformans*), coccidioidomycosis (*Coccidioides immitis*), and blastomycosis. Ricketts concluded that these were similar diseases with different clinical manifestations and there was enough similarity to state that, if not caused by the same organism, the agents were sufficiently related to be in the same genus. He conceded that thrush (*Candida albicans*) and sporotrichosis (*Sporothrix schenckii*) were different disease entities.

Ricketts described 12 new cases of blastomycosis with a review of their clinical courses, therapy, attempts at serology, and exquisite histopathological details on each patient. He recognized the mycelial and yeast forms of the organism and noted that the mycelial form never appeared in tissue. On one patient, he provided the first histological report of both 'small forms' (4–6 μm) and 'large forms' (20–30 μm) of *B. dermatitidis* in potassium hydroxide (KOH) preparations from fresh tissue. Unfortunately, the cultures from this patient did not grow. Cultures from tissue of another patient, however, were incubated in both a 'brood oven' incubator and the laboratory at room temperature. He described the differences in gross colonial morphology between the two cultures but did not present a microscopic comparison. The brood oven culture was described as having the appearance of 'a heap of earth worms.' He also failed to recognize that temperature was the cause for the two forms.

The thermal basis for dimorphism was first described by Hamburger in 1907 (Hamburger 1907). He specifically reported that the incubator temperature was 37°C and that room temperature varied between 16°C and 24°C. The gross colonial morphology and the microscopic characteristics of both forms were described. He converted the mycelial form of *B. dermatitidis* to the yeast form and vice versa simply by changing the temperature of incubation. Hamburger stated that temperature is the most important factor for this transformation in morphology, and recommended that duplicate cultures of clinical material should be made to accommodate growth at either temperature (see below).

In 1914, Stober published the first attempts to define the ecology and epidemiology of blastomycosis (Stober 1914). From his investigation of the social aspects of several of the patients and his personal inspection of their residence, he made some observations on the probable source of infections. Many patients, Stober reported, lived in close proximity to damp earth, rotted wood, and wet, cardboard-lined walls. He also associated blastomycosis with plumbers who allegedly came in contact with the mold on timbers in cellars where they worked. He grew a white mold from one of the homes but did not provide sufficient mycological features of the isolate to show that this was *B. dermatitidis*. Thus, Stober probably performed the first ecological studies of *B. dermatitidis* and was the first investigator to recognize the ecological association of this mold with the environment. His environmental observations are similar to the associations we make today with the probable natural reservoir of *B. dermatitidis*. This paper also provided a thorough study of the pathological, mycological, and clinical features of systemic blastomycosis. He described the course of the illness in patients as well as the therapy and prognosis of this mycosis.

ECOLOGY

Knowledge of the ecology of the etiologic agent is essential for the investigator to understand the epidemiology of blastomycosis. Although blastomycosis and its specific etiologic agent, *B. dermatitidis*, were first described in 1894, the mystery of the precise ecological niche occupied by this terricolous fungus remains unresolved. The natural reservoir of the three other major systemic fungal pathogens was firmly established by the middle of the twentieth century. *C. immitis* was associated with the deserts of the southwestern USA and northwestern Mexico in 1932 (Stewart and Meyer 1932), *Histoplasma capsulatum* var. *capsulatum* was isolated from infested soil in 1949 (Emmons 1949), and the association of *C. neoformans* with pigeon droppings has been known since 1951 (Emmons 1951). The ecological niche of *B. dermatitidis* cannot be described with certainty but there is sufficient evidence to describe the probable habitat. The first isolation of *B. dermatitidis* from nature was not reported until 1961 (Denton et al. 1961). The fungus was found in a collection of soil, tobacco, and organic debris

obtained in a tobacco-drying barn in Lexington, KY, USA. However, it was later found that the outbuilding from which the fungus was isolated had formerly housed a dog with blastomycosis. Although this isolation did not establish the ecological niche of this organism, it did prove the value of the investigational method used to recover the agent and demonstrated that *B. dermatitidis* could survive in certain soil for at least 2 years.

Isolation from nature

There have been only a few credible reports of the isolation of this fungus from a natural habitat (Denton et al. 1961; Denton and Di Salvo 1964, 1979; Bakerspigel et al. 1986; Klein et al. 1986, 1987a; Baumgardner and Paretsky 1999). Each of these isolations was made from material that was rich in organic matter including animal feces, dust, plant fragments, minerals, or insect remains. The environmental samples usually contained soil, or were near the soil. The epigeal substrate from which the fungus has been isolated was moist, shaded from direct sunlight, mixed with organic material, and with a pH of less than 6.0. A more specific ecological association for *B. dermatitidis*, as with *H. capsulatum* var. *capsulatum* and *C. neoformans*, is not yet apparent.

Environmental isolations

In 1964, Denton and Di Salvo reported the first isolation of *B. dermatitidis* from naturally contaminated environmental sites (Denton and Di Salvo 1964). Of 356 samples collected along the flood plain of the Savannah River in Augusta, GA, USA, 10 yielded the fungus. The samples were collected in abandoned sheds which had previously provided shelter to mules, chickens, dogs, or rabbits. Persistent attempts to re-isolate the geophilic fungus from the positive sites were not successful. Only one site yielded the fungus from a sample collected 10 months later (Denton and Di Salvo 1979).

In 1986, Klein et al. reported the isolation of *B. dermatitidis* from a beaver lodge located in Eagle River, WI, USA, in association with an outbreak of blastomycosis among a large number of school children (Klein et al. 1986). This was the first account of an isolate in direct association with human infection and confirmed what was long suspected: the source of infection for blastomycosis was a saprophytic mold in nature. In the same year, Bakerspigel and associates reported the isolation of *B. dermatitidis* from a patient with systemic disease who worked in a shed in Ontario, Canada (Bakerspigel et al. 1986). The shed contained large amounts of diatomaceous earth and the air was often dusty. To control this dust, the area was sprinkled with water on a daily basis. After soil sampling at this worksite, these investigators were successful in isolating *B. dermatitidis* from the environment. In 1987, Klein et al. reported the isolation of *B. dermatitidis* from soil collected at two new sites in Wisconsin where additional outbreaks of blastomycosis had occurred (Klein et al. 1987a). The patients in both these latter outbreaks were involved with the disruption of soil. Thus, it has been shown without a doubt that *B. dermatitidis* is an edaphic organism. In 1999, Baumgardner and Paretsky reported the isolation of *B. dermatitidis* from environmental material. The samples were collected from a woodpile located near a dog kennel, which housed dogs with a confirmed diagnosis of blastomycosis. The significant feature of this isolation is that, for the first time, the organism was isolated from the environment using an in vitro method (Baumgardner and Paretsky 1999).

Water association

Some investigators claim that the ecological niche of *B. dermatitidis* has an association with water. There has been some support for this hypothesis from both epidemiologic and experimental studies. The first isolates of *B. dermatitidis* from nature came from the alluvial flood plain of the Savannah River (Denton and Di Salvo 1964). In 1969, Borelli and his colleagues described the distribution of the fresh water salamanders of the genus *Necturus*, which coincided with the distribution of patients with blastomycosis in the USA. They suggested that these salamanders may play a role in the ecology of *B. dermatitidis* (Borelli et al. 1969). Furcolow et al. published an extensive investigation of the prevalence and incidence of *B. dermatitidis* in dogs and human beings (Furcolow et al. 1970). They reviewed the literature from 1885 until 1968 and found a high prevalence of human and canine cases south of the Ohio River and east of the Mississippi River. From an analysis of these findings they hypothesized an ecological relationship between *B. dermatitidis* and the proximity to water.

The conidia of *B. dermatitidis* are difficult to separate from their conidiophores. McDonough et al. demonstrated that the conidia are readily released from the mycelium in the presence of moisture (McDonough et al. 1976). Subsequently, McDonough and Kuzma, in an epidemiologic study of blastomycosis in Wisconsin, found that many of the human and canine subjects lived near bodies of water. This led them to suggest that foggy weather may contribute to the release of conidia in nature and the infection of susceptible hosts (McDonough and Kuzma 1980).

Archer also studied canine blastomycosis in Wisconsin (Archer 1985). He found that 68 percent of the 200 dogs with this mycosis lived within 500 meters of water. In a similar account from Canada, Harasen and Randall reported the location of eight dogs with blastomycosis in a small town in Saskatchewan (Harasen and Randall 1986). The dogs all resided within two blocks of a creek, which was a resting place for migrating Canada geese

(*Branta canadensis*). Thus, three purported requirements for the ecological niche of *B. dermatitidis* in nature were satisfied (soil, moisture, and organic material). Bakerspigel et al. isolated *B. dermatitidis* from the soil in a workshed in which there was a constant spray of water for dust control. The atmosphere had essentially 100 percent humidity (Bakerspigel et al. 1986). Finally, six of the 13 outbreaks of human blastomycosis occurred along rivers or lakes in the USA.

Geographical distribution

The geographical distribution of histoplasmosis and coccidioidomycosis has been defined by the use of skin test surveys, soil isolations, and serological studies. But these tools have not been available for the investigation of blastomycosis. Neither the skin test nor the serological antigens have sufficient specificity to be reliable, and the methods available to isolate *B. dermatitidis* from natural substrates, utilizing animal inoculation, are cumbersome and have a low sensitivity. The present understanding of the geographical distribution of *B. dermatitidis* comes from published case reports and a few outbreaks which attracted investigation.

These reports and studies usually reflect the interest of clinicians, epidemiologists, and mycologists who publish their experiences, rather than a true reflection of the distribution of *B. dermatitidis*. From the investigations of the outbreaks listed above, it can now be said with some certainty that the desiccation of the substrate, followed by a disturbance of the site by anthropurgic activity or natural phenomena (wind or storms), results in the creation of an aerosol of infectious particles. From a detailed review of the literature and careful interpretation of the evidence, it appears that autochthonous cases of blastomycosis occur in North America and Africa with a possible focus in central India (Figure 1). First thought to be restricted to the North American continent, sporadic case reports of blastomycosis from various parts of the world began to appear in the 1940s. Many of these reports were the result of erroneous identification of the etiologic agent resulting from incomplete studies of the isolate. Other reports did not present sufficient data to validate the claim that these were autochthonous cases. Di Salvo reviewed the original publications of all reports of blastomycosis from outside the USA (Di Salvo 1992a). Each case was re-examined as to the details of diagnosis. Those with insufficient diagnostic information (clinical, cultural, or histological) were discarded. The remaining reports in that publication present the current knowledge of the geographical distribution of *B. dermatitidis*.

With culture and tissue confirmation it became clear that Africa was an endemic area for this arcane mycosis. There have been scattered reports of autochthonous cases of blastomycosis from the Middle East and Europe, but these involved a small number of patients and, in some cases, insufficient information was presented to make a definitive statement of endemicity. It is curious that in North America, the disease occurs almost exclusively east of the 100th meridian which is approximately through the center of the USA (Figure 2). There has been a recent report of two patients with blastomycosis from Colorado who were both involved with the relocation of prairie dogs. Although the two patients previously resided in the

Figure 1 *Worldwide distribution of patients with documented evidence of blastomycosis. Detailed maps of each of these areas appeared in a previous publication (Di Salvo 1992a). (From Di Salvo 1992a, with permission. Copyright by South Carolina Department of Health and Environmental Control)*

Figure 2 *The 100th meridian passes through the center of the USA and Canada. This figure also shows the location of the 13 documented outbreaks of blastomycosis (Di Salvo 1992b). (From Di Salvo 1992b, with permission. Copyright by South Carolina Department of Health and Environmental Control)*

endemic area, circumstantial evidence (temporal onset, substantial disruption of soil, and excess rainfall immediately preceding the anthropurgic activity), despite lack of antibody evidence and negative soil sampling, is convincing that these were autochthonous cases (Hannah et al. 2001). This finding suggests that a previous patient with blastomycosis from Colorado may have also been an autochthonous case of this mycosis instead of reactivation from residency in the endemic area more than 50 years previously (Ehni 1989). The number of cases is extensive in the USA, and moderate in Canada, with only one well-documented patient from Mexico.

There is a need for a simpler, more efficient, in vitro method to isolate or identify the etiologic agent of blastomycosis in the environment. Until this is available much of the ecology of *B. dermatitidis* will remain speculative.

EPIDEMIOLOGY

The infectious particles of *B. dermatitidis* are its mycelial fragments and conidia; the respiratory system is the portal of entry. Particles which are between 0.5 and 5.0 μm can readily pass through the respiratory tract and enter the alveoli of the lungs. The conidia of *B. dermatitidis* vary in size from 2.0 to 10 μm and the mycelial fragments may be even smaller; thus these particles can readily reach the alveoli of humans and other animals. When the host's resistance fails, an infectious process is established. Garrison and Boyd presented in vitro evidence to demonstrate the conversion of the conidia to yeast-like cells (Garrison and Boyd 1978), whereas Denton and Di Salvo demonstrated the infectivity of conidia in vivo (Denton and Di Salvo 1968). The incubation period for blastomycosis is 4–8 weeks after an inhalation exposure and a clinical dermal lesion will be obvious 1–5 weeks after a trauma (Di Salvo 1992b).

Seasonality

A substantial number of publications, which reported the time of year when cases of *B. dermatitidis* occurred, have been reviewed (Di Salvo 1992b). Each of these

papers surveyed a large number of human beings or dogs with blastomycosis. From this analysis, there does not appear to be any seasonal occurrence of this mycosis. The evidence is difficult to evaluate because the time of exposure or onset of illness usually cannot be determined with any accuracy. Cutaneous lesions may appear at various intervals after the initial exposure, which is frequently unknown; pulmonary infection may be asymptomatic or unrecognized and there may be prolonged time lapses before a definitive diagnosis is made.

Occupational risk

No association can be made between *B. dermatitidis* and a specific occupation. Ten selected papers published between 1955 and 1988 were reviewed (Di Salvo 1992b). Each paper reported on a large series of patients in which occupation was specified. There were a total of 771 patients with blastomycosis in the analysis. It was obvious that most of the victims of this disease had an occupation or avocation involving outdoor activity. There are many additional single case reports of individuals with an environmental exposure to wood or soil who became infected with *B. dermatitidis*. Thus, it is not the specific occupation that renders a person susceptible to infection with *B. dermatitidis*, but the exposure of an individual to the probable ecological niche of the fungus.

Age, race, and gender

There is no recognized age, race, or gender susceptibility. People of all races and all age groups, male or female, are susceptible to this mycosis. The predominance of patients in the fourth, fifth, and sixth decades of life is consistent with an occupation or avocation that places these individuals at greater exposure to the elusive environmental niche of this fungus. A similar reasoning can be applied to the gender of the patients. Males may be infected more than females, but this bias reflects the workforce more probably exposed to the natural nidus of *B. dermatitidis* or the greater male orientation in the past to outdoor activities. Unlike coccidioidomycosis, race susceptibility for *B. dermatitidis* is not evident. Each report of such predilections merely reflects the population at risk or being studied (Di Salvo 1992b).

Transmission

It is generally accepted that the respiratory system is the portal of entry for all forms of blastomycosis except direct transcutaneous inoculation (Schwarz and Baum 1951). Blastomycosis is not ordinarily transmitted from person to person or animal to human. With the exception of one report in which two young men working side by side acquired pulmonary disease, there has been no evidence of aerosol transfer (Procknow 1966). The two patients had no other association except at work, thus leading the investigator to believe that there may have been human-to-human transmission. Exposure to the same environmental source of *B. dermatitidis* at the worksite was not absolutely ruled out. There have been two reports with strong evidence to support transplacental passage of *B. dermatitidis* (Watts et al. 1983; Maxson et al. 1992) and two well-documented cases of conjugal transmission of blastomycosis (Farber et al. 1968; Craig et al. 1970; Dyer et al. 1983).

Transcutaneous blastomycosis caused by accidental inoculation through dog bites during examination or treatment is an occupational hazard of veterinarians. There are several well-documented reports of humans becoming infected from animals in this way (Di Salvo 1992b). Two other reports of transmission from dogs to humans were, most probably, a common exposure to a contaminated site of *B. dermatitidis* (Schwartzman et al. 1959; Lieberman 1963). Similarly, pathologists have acquired infections with *B. dermatitidis* through the percutaneous route by self-inoculation during a postmortem examination of a patient with the infection (Di Salvo 1992b).

Skin test

There is currently no reliable skin test available for *B. dermatitidis*. The dermal hypersensitivity to fungal antigens has been a significant tool for delineating the geographical distribution of *H. capsulatum* var. *capsulatum* and *C. immitis*. Information gleaned from these studies has also established the prevalence of the asymptomatic disease caused by these agents. Unfortunately, the delayed-type hypersensitivity skin test antigen for blastomycosis has not been useful. The crude extracts, made from either the mycelial form (blastomycin) or the yeast form of the organism, have had the same deficiencies as the serological tests: a lack of sensitivity and specificity.

The blastomycosis skin test has presently been abandoned by the medical community because it is not suitable for either diagnostic or epidemiologic studies. For these reasons the US Food and Drug Administration (FDA) removed the product from the US market in 1972.

Many scientists have endeavored to develop an improved skin test antigen through the development of purified chemical extracts of specific antigenic fractions, but a successful product has yet to be achieved. Recent studies by Abuodeh and Scalarone have produced encouraging results with regard to the development of a useful skin test antigen (Abuodeh and

Scalarone 1994, 1995). Preparations from a yeast-form isolate were efficacious with respect to their sensitivity to delayed-type hypersensitivity responses in *B. dermatitidis*-sensitized guinea pigs; but there was cross-reaction in animals sensitized with the *capsulatum* variety of *H. capsulatum*. Additional studies with a more purified derivative elicited a more specific reaction (Bono et al. 1995). These investigations may lead to the development of a useful epidemiologic tool in the future.

Animal disease

Next to humans, dogs are the most frequent animal infected with *B. dermatitidis*. Canines, as a surrogate for humans, have served as sentinels for human disease in epidemiologic studies for many years. Menges and his colleagues reported on an extensive study of canine and human blastomycosis in 1965 (Menges et al. 1965). The results of that study indicated that both humans and dogs were exposed to the same natural nidus of *B. dermatitidis* where they inhaled the infectious particles. These investigators also concluded that there was no evidence of animal-to-human transmission. Similar studies have supported these conclusions and have shown that in the endemic areas for blastomycosis, both dogs and humans have a similar geographical distribution of the disease (McDonough and Kuzma 1980; Archer et al. 1987; Baumgardner et al. 1995). Canine blastomycosis has been called the harbinger of human blastomycosis (Sarosi et al. 1979). Legendre has reviewed animal blastomycosis in detail (Legendre 1992).

MYCOLOGY

Nomenclature

The etiologic agent of blastomycosis is the thermal dimorphic species *B. dermatitidis* (Gilchrist and Stokes 1898). It has long been recognized that this binomial is taxonomically incorrect. This specific epithet, first used by Gilchrist and Stokes in 1898, has had several synonyms proposed over the years. All have been rejected (Conant 1939). Although medical mycologists agree that *B. dermatitidis* does not conform to the taxonomic code, the traditional, long-time use of the binomial has justified its continued use.

Identification

An isolate of *B. dermatitidis* is identified by several morphological characteristics. The classic means of identification is the in vitro conversion of this dimorphic fungus from the yeast form to the mycelial form and/or vice versa. Temperature variation is the method used to demonstrate the thermal morphological change. Incubation of yeast colonies on SGA at 25–30°C will yield growth of the mycelial form of the mold in 10–14 days. Conversely, the cultivation of mycelium on an enriched medium, such as brain–heart infusion agar with 5 percent blood (see Laboratory diagnosis), and incubation at 37°C will yield yeast colonies in 3–5 days.

The culture of *B. dermatitidis* from clinical material requires 2–4 weeks for growth at 25°C on SGA. The typical colony of most isolates of *B. dermatitidis* is a white, aerial, cottony, filamentous mold. The colony may vary from a flat, dull colony of mostly vegetative hyphae to a heaped fungal mass with hyphal tufts. After 2–3 weeks the culture usually becomes more typical in appearance. The mycelial-form colony is white in the early stages of growth but may become tan to light brown as the colony ages. Concentric rings of growth are frequently seen in older colonies, i.e. 4–8 weeks of age (Figure 3).

Microscopically, the mycelium and the asexual propagules (conidia) are evident. The hyphae are narrow (6–7 μm wide), hyaline, branching, septate mycelia. New growth occurs at the hyphal tip. The unicellular conidia are formed on thin, lateral conidiophores or directly on the hyphae (sessile). They are slightly oval to round with a smooth wall and vary from 3 to 6 μm in diameter. These structures are readily seen in a slide culture or a wet mount preparation. *B. dermatitidis* cannot, however, be identified solely by its microconidia, which are

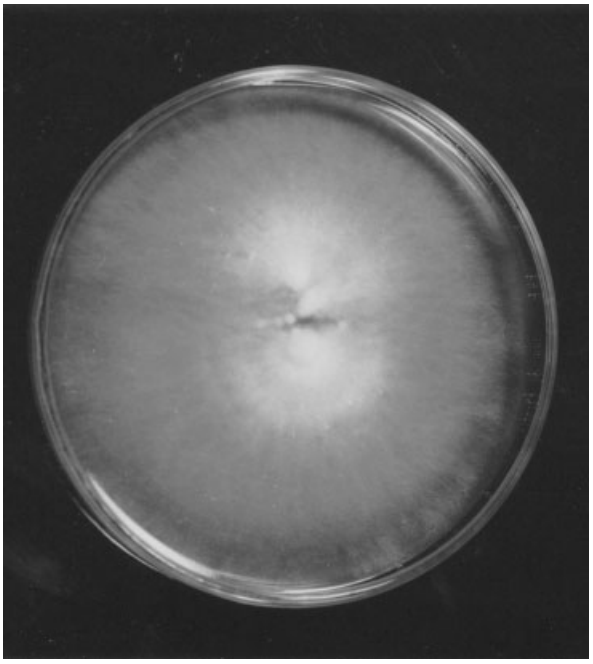

Figure 3 Blastomyces dermatitidis *mycelial form colony on Sabouraud's glucose agar. Note the concentric rings of growth. This colony, incubated at 25°C, was about 4 weeks old.*

indistinguishable from those of many other fungal saprophytes and pathogens (Figure 4).

At 37°C the yeast-like, or tissue, form grows in about 7–10 days when cultured on enriched media (usually brain–heart infusion agar containing 5 percent blood). The colony appears as a buttery-like, cerebriform, soft colony with a tan color. A wet mount in lactophenol cotton blue can be prepared from the culture. Microscopic examination shows typical yeast cells, 8–12 μm in diameter, with a thick wall (frequently referred to as a 'double wall') and a single bud with a wide base of attachment to the mother cell, characteristic of this species (Figure 5). Electron microscopy studies have shown that the cell wall consists of two layers separated by a clear zone (Daniel et al. 1979). The yeast forms contain two to four nuclei per cell (Clemons et al. 1991) while the conidia are uninucleate.

The yeast cells, when found without buds, may be confused by less experienced laboratorians with the immature spherules of *C. immitis*, the yeast forms of *H. capsulatum* var. *duboisii*, *C. neoformans*, or an unbudded yeast-form cell of *Paracoccidioides brasiliensis*.

A defining characteristic of *B. dermatitidis* and several other dimorphic fungi is the fact that their yeast forms will convert into mycelial forms when incubated at 25°C and, conversely, mycelial forms can be changed to the yeast forms when incubated at 37°C. Many strains of *B. dermatitidis* do not readily convert to the yeast form. Several transfers, 3–4 days apart, aid in the transformation, although sometimes the transformation is not complete and transitional forms are seen (Figure 6).

There are no diagnostic biochemical tests which will aid in the identification of the yeast or mycelial forms of *B. dermatitidis*. Morphology is the preliminary or presumptive method of identification and the specific nucleic acid probe is confirmatory.

Teleomorph

Ajellomyces dermatitidis, the ascomycetous or sexual state of this pathogen, was first described by McDonough and Lewis (1968) . It is a heterothallic member of the family *Gymnoascaceae*. The perfect state is characterized by its globose gymnothecia with spiralled hyphae radiating from their centers. A network of secondary peridial hyphae develops from the spirals. When mature, the tan gymnothecia measure 200–350 μm in diameter. The hyaline, evanescent asci produced in the gymnothecia contain eight smooth, spherical, hyaline, or light-tan ascospores that are uninucleate and measure 1.5–2.0 μm in diameter. It is interesting to note that the teleomorph of *H. capsulatum* is in the same genus as that of *B. dermatitidis*.

African forms

The autochthonous isolates of *B. dermatitidis* from Africa are similar to each other and appear to be distinct from North American isolates (Di Salvo 1992b). It has been suggested that isolates from these two different parts of the world are probably the same species, but different serotypes. McDonough crossed African isolates with North American isolates with the production of cleisothecia that lacked ascospores, thus indicating that the two isolates were closely related but not unequivocally the same species (McDonough 1970). However, four African strains studied by Kwon-Chung

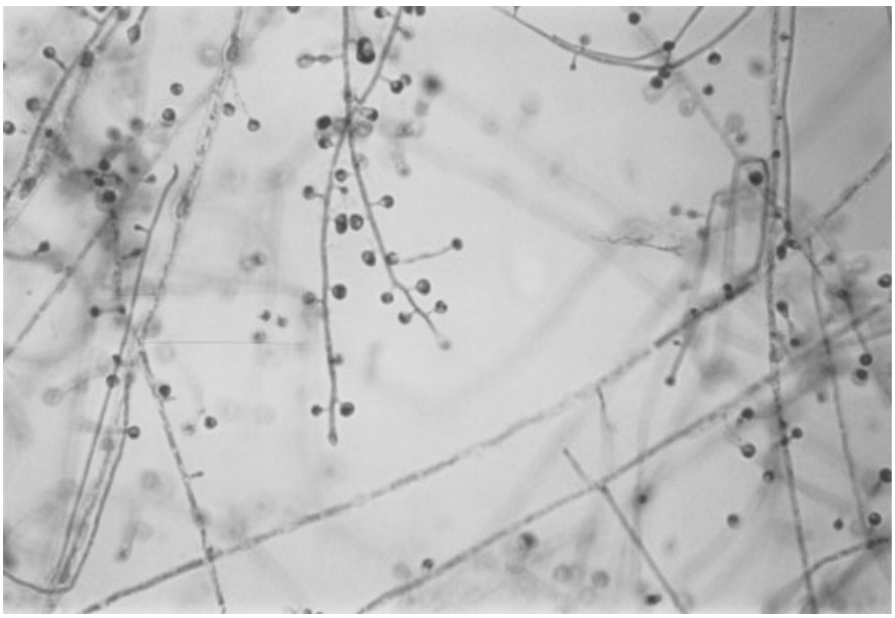

Figure 4 *Microscopic view of* Blastomyces dermatitidis *mycelium and conidia. Agar at 25 C,°13 days old. Magnification* × *112*

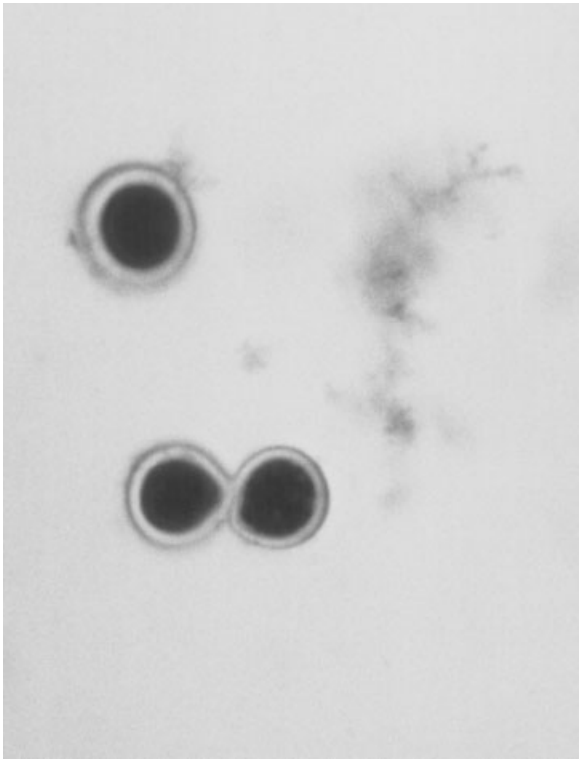

Figure 5 *Microscopic view of the yeast form of* Blastomyces dermatitidis *in a methylene blue wet mount. Note the figure-of-eight appearance of two cells of equal size. The broad base of attachment, single bud and 'double contour' wall are obvious. Magnification × 160*

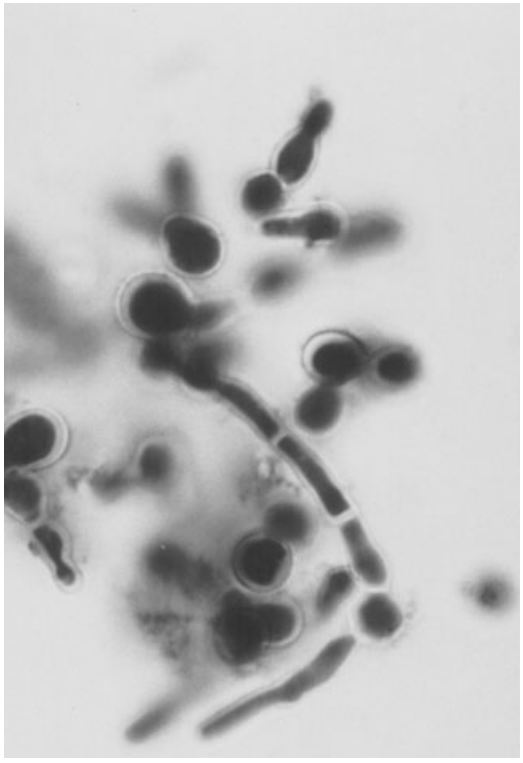

Figure 6 *Conversion of the mycelial form of* Blastomyces dermatitidis *to its yeast-form by incubation at 35°C. Note that the conversion was not complete on the first transfer. Some fragments of mycelium are seen intermingled with the yeast forms. At 48 hours; magnification × 160*

did not cross with her North American tester strains (Kwon-Chung 1971).

Sudman and Kaplan investigated the antigenic relationship between North American and African strains of this fungus using fluorescent antibody reagents (Sudman and Kaplan 1974). The conclusion of this study was that, although the strains share certain antigens, the isolates from these two geographical areas were antigenically different. Kaufman et al. (1983) examined the exoantigens of a large number of strains of *B. dermatitidis* from various parts of the world. They reported that the African isolates did not produce the A exoantigen which was evident in all other isolates. They also described gross and microscopic differences in the colonial morphology between African and North American isolates. Some African strains have echinulate conidia as opposed to the smooth-walled conidia of North American strains. These investigators concluded that there are two serotypes of *B. dermatitidis*.

Vermeil et al. (1982), in a comparative study of these geographically distinct strains, reported that the conidia from the African strains were gathered in clusters. They also observed that the mycelial form of the African strains did not convert to the yeast form as readily as the North American strains. Using the enzymatic activity of the yeast-form as a biotyping tool, Summerbell et al. (1990) failed to show any differences between two African strains and 18 North American strains based on these criteria. The taxonomy and biology of *B. dermatitidis* were recently reviewed by Sugar (1992).

Biochemistry

Comparative studies on the chemical composition of yeast and mycelia have enhanced understanding of the biochemistry of *B. dermatitidis*. Lipids make up about 9 percent of the dry weight of yeast cells (Beck and Hauser 1938). About 75–80 percent of extractable lipids from yeast and mycelia are oleic and linoleic acids. Oleic acid predominates in yeasts, while a higher percentage of linoleic acid is recovered from mycelia (Domer and Hamilton 1971). Studies to localize lipids found that about 2 percent of the yeast cell wall was lipid, while negligible lipid was found in the mycelial cell wall. The lipid content of yeasts is interesting, as several studies have noted differences in lipid content between virulent and avirulent isolates of *B. dermatitidis*. Lipid content directly correlated with virulence of the isolate in mice in one study (Di Salvo and Denton 1963). However, in another study, a spontaneous avirulent mutant had a three- to fourfold increase in total lipid content,

primarily composed of an increase in fatty acids, when compared to the virulent strain (Brass et al. 1982).

Other differences in cell wall composition between yeast and mycelia have been studied in an effort to understand dimorphism and virulence. The cell walls of both yeast and mycelia contain chitin and glucan. The glucan in yeast cells is 95 percent α-glucan, while that of mycelia is 60 percent α- and 40 percent β-glucan (Kanetsuna and Carbonell 1971). This shift in predominant type of glucan is similar to *P. brasiliensis* and is thought to be secondary to activation of α-glucan synthase with increased temperature (Kanetsuna et al. 1972). The chitin isolated from *B. dermatitidis* mycelia is similar to chitin obtained from *H. capsulatum* and *P. brasiliensis* (Gow and Gouday 1983). Chitin is a stable cell wall component during dimorphic change. Its role in dimorphism is suggested by electron microscopic studies showing different chitin fibril arrangements in yeast and mycelial cell walls. In yeast, the chitin fibrils are noted to be tightly interwoven in a random orientation, while in mycelia, they are arranged in a more longitudinal manner in many areas of the cell wall (Kanetsuna 1981). Isolation of the enzyme chitin synthetase from the yeast and mycelial forms indicates similar biochemical characteristics, but the yeast form enzyme is in latent form requiring activation by protease, whereas the mycelial form enzyme is in active form (Shearer and Larsh 1985).

The dimorphism of *B. dermatitidis* is primarily temperature-dependent. However, studies into the mechanism of dimorphic transition indicate a more complex regulation other than by temperature alone. Yeasts grown at 37° C can revert to mycelia in the presence of cAMP phosphodiesterase inhibitors, theophylline, or 3-isobutyl-1-methylxanthine. Using electron microscopy to study yeasts at 37°C, cAMP phosphodiesterase is localized to nuclear and mitochondrial membranes and to endoplasmic reticulum and vacuolar areas. By contrast, similar studies of the yeast 24 hours after lowering the incubation temperature to 25°C show decreased enzyme activity of cAMP phosphodiesterase in vacuolar areas. This suggests that increased levels of intracellular cAMP may be required for dimorphic transition to the yeast form (Paris and Garrison 1984). Other physiological changes that occur with mycelial to yeast transition upon change of temperature are related to mitochondrial respiration. Three stages in the transition are described:

1. immediately after an increase in temperature, partial or complete uncoupling of oxidative phosphorylation, leading to decreases in ATP levels, respiration rate, and electron transport components
2. a dormant period of 4–6 days with absent to low rates of respiration
3. a recovery phase marked by increase in respiration, increased ATP, and electron transport components and the appearance of yeast cell morphology.

During stage 2, the presence of cysteine is required for the operation of the sulfhydryl-induced shunt pathway. These stages of form transition are shared by *H. capsulatum* and *P. brasiliensis* (Medoff et al. 1987). Nutritionally dependent dimorphism is also indicated by reported conversion of mycelial to yeast form at 26°C on partially defined media.

HOST RESPONSES

Clinical forms

There are two clinical forms of blastomycosis: cutaneous and systemic or disseminated disease. It was thought that these were two clinically distinct syndromes until 1951 when Schwarz and Baum (1951) clearly demonstrated that the common cutaneous form is largely a manifestation of active or inactive systemic disease.

CUTANEOUS DISEASE

Cutaneous blastomycosis may be a primary transcutaneous disease or secondary to systemic infection. Primary transcutaneous blastomycosis is the result of the direct inoculation of *B. dermatitidis* into the skin, and therefore it is commonly seen as a solitary lesion. This type of disease is unusual and frequently occurs as the result of an accidental inoculation. It is considered an occupational hazard for mycologists, pathologists, and veterinarians (Schwarz 1983). There have been several reports of laboratory accidents which occurred during the course of experimental studies. Accidental self-inoculation during postmortem examinations of patients who have died from blastomycosis has also been reported. Similarly, veterinarians are at risk from transcutaneous inoculation as a result of accidents which occur during postmortem examinations, surgery, or when bitten by animals, usually dogs, infected with *B. dermatitidis*. As the accidents occur when working with the organism or infected tissue, most inoculations occur on the hands (Schwarz 1983). When first noted, the wound site is tender and inflamed. The lesion starts as a papule and promptly develops into a pustule; lymphangitis or regional lymphadenopathy may or may not occur, but the progression of the infection stops at the axilla. There are usually no constitutional symptoms and the course of disease is self-limited. The lesions heal spontaneously in several weeks to several months, and systemic antifungal therapy is not required. The pus from the lesions contains many yeast form cells which are readily visible in KOH wet mounts. This observation, together with knowledge of the previous trauma, is diagnostic. The incubation time for transcutaneous inoculation blastomycosis is from 1 to 5 weeks (Di Salvo 1992b).

Secondary cutaneous blastomycosis occurs as a result of the hematogenous spread of infection from another

focus, usually the lungs; therefore the lesions are frequently multiple. Although cutaneous lesions result from disseminated blastomycosis, the initial pulmonary disease may not be obvious and the cutaneous lesions may be the only presenting symptoms. This cutaneous manifestation may occur spontaneously or develop at the site of a subsequent injury. The eliciting trauma may be as slight as a bump to an extremity, where transient circulating blastomycetes localize in the damaged tissue. The skin lesions appear as indolent, ulcerated, or verrucous lesions and may resemble a malignancy. Typically a lesion ulcerates and heals with scarring. Generally there is a sharp edge at the periphery of the lesion where invasive activity is occurring. The boundary frequently consists of minute abscesses which often serve as a good source of clinical material for direct examination or culture. Healing is obvious in the central area. As opposed to primary inoculation blastomycosis, the regional lymph nodes are not involved in secondary cutaneous blastomycosis (Figure 7).

SYSTEMIC DISEASE

The systemic disease takes many clinical forms. Acute primary pulmonary blastomycosis probably occurs more frequently than is reported. The symptoms are those of an influenza-like illness with fever, chills, and a productive cough, and chest x-rays will show nonspecific pulmonary disease. The etiology is usually not suspected and, if considered, the patient is closely observed without the administration of therapy. Untreated, acute pulmonary blastomycosis may be self-limited and resolve within a month or progress to chronic pulmonary disease or systemic disease. The diagnosis of acute primary pulmonary blastomycosis is frequently made retrospectively when the disease progresses to the chronic form of pulmonary infection, secondary cutaneous lesions develop, or the patient is recognized as a member of a cohort exposed at a common point source. The incubation period of blastomycosis acquired by the respiratory route is 4–8 weeks (Di Salvo 1992b).

Figure 7 *This patient has a cutaneous lesion of secondary blastomycosis. Six months before the appearance of the lesion, he experienced an acute, undiagnosed, pulmonary infection.*

The most common form of pulmonary blastomycosis is a slowly progressing chronic pneumonia which persists for many months. The symptoms consist of fever, chills, cough, chest pain, hemoptysis, night sweats, and weight loss. The differential diagnosis includes tuberculosis, histoplasmosis, coccidioidomycosis, other non-infectious forms of chronic lung disease, and malignancy. Pleural effusions do occur, but they are an unusual manifestation of blastomycosis (Jay et al. 1977; Kinasewitz et al. 1984; Failla et al. 1995).

Although pulmonary and cutaneous manifestations are the most common form of the disease, there have been many reports of infection of practically every other organ. Systemic blastomycosis may be limited to the lungs or, if disseminated, involve almost any organ in the body. Dissemination may occur by the hematogenous, lymphatic, or direct extension routes (Schwarz and Baum 1951) and the symptoms vary according to the organ systems affected by the disease.

Miliary blastomycosis is an unusual systemic manifestation of this fungous infection. The symptoms consist of a rapid onset of severe dyspnea and respiratory failure due to adult respiratory distress syndrome (ARDS). The sporadic occurrence of this rare form of blastomycosis is considered a medical emergency and the outcome is frequently fatal. An aggressive therapeutic regimen is imperative if the patient is to survive (Shaw et al. 1976; Rippon et al. 1977; Griffith and Campbell 1979; Stelling et al. 1984; Renston et al. 1992; Meyer et al. 1993). It is thought that this clinical entity may represent endogenous reactivation (Berger and Kraman 1981; Stelling et al. 1984).

The male urogenital system seems to be highly susceptible to blastomycosis. This includes the kidney, prostate, testes, epididymis, and seminal vesicles. The prostate is frequently involved whereas the urinary bladder itself is rarely infected. Prostatitis caused by *B. dermatitidis* was extensively reviewed by Schwarz (1982).

Osteomyelitis is a frequent complication of blastomycosis (Denton et al. 1967) and arthritis may be the presenting symptom in disseminated blastomycosis (George et al. 1985; Robert and Kauffman 1988). Blastomycosis of the central nervous system, although not common, does occur. Pleocytosis is usually lymphocytic (Carmody and Tappen 1959; Buechner and Clawson 1967), although a largely polymorphonuclear response has been reported in one patient (Harley et al. 1994). Blastomycosis of the larynx, adrenals, heart, eye, paranasal sinuses, tongue, uterus, ovary, etc., has also been

reported. The liver, spleen, and gastrointestinal tract are only rarely involved.

REACTIVATION BLASTOMYCOSIS

It has been suggested that reactivation of latent blastomycosis can occur. Several observations support this concept which is well documented in tuberculosis. Subsequent to the course of benign self-limited disease, in some patients a period of clinical and radiological resolution of the mild pulmonary symptoms has been reported. At some later time, ranging from months to years, the patients exhibit signs of systemic blastomycosis (Laskey and Sarosi 1978). It was reported that one patient, from Colorado, developed fatal progressive pulmonary blastomycosis 40 years after leaving the endemic area (Ehni 1989). However, as a result of a subsequent report of two patients with proven blastomycosis from Colorado, which has been considered outside the endemic area, reactivation disease in that patient should be reconsidered (Hannah et al. 2001). The source of the sequestered organisms, unlike tuberculosis, is not known. Such occurrences reinforce the admonition that a careful patient history is essential when an endemic fungal disease is suspected. There is insufficient evidence to determine if exogenous reinfection occurs.

SUBCLINICAL DISEASE

It is becoming more apparent that there is a form of blastomycosis that is subclinical or an acute, mild, self-limited disease (Denton et al. 1967; Recht et al. 1979; Sarosi et al. 1986; Vaaler et al. 1990). This concept has been reinforced during studies of common source outbreaks of blastomycosis (Sarosi et al. 1974; Centers for Disease Control 1979; Klein et al. 1986). The diagnosis of asymptomatic patients was determined while investigating a cohort of exposed individuals. Many of these individuals recovered spontaneously from their illness. The only evidence of *B. dermatitidis* infection was detected by antigen-specific immune studies, serological testing, and an abnormal chest x-ray. In some instances, the revelation of a previous history of pulmonary disease, compatible with blastomycosis, was revealed after the diagnosis of systemic blastomycosis was confirmed.

OPPORTUNISTIC INFECTIONS

B. dermatitidis may act as an opportunistic fungus in immunocompromised patients. Sporadic cases of blastomycosis in such patients were reported before 1990. In most patients, the underlying conditions were hematological malignancies and corticosteroid therapy (Schwarz and Salfelder 1977; Recht et al. 1982). Additional patients with blastomycosis, who were compromised by sarcoid, renal transplants, and Hodgkin's disease, have also been reported (Önal et al. 1976; Chow et al. 1981; Hii et al. 1990; Winquist et al. 1993).

The number of acquired immunodeficiency syndrome (AIDS) patients with blastomycosis is limited when compared with those patients superinfected with the other systemic fungi. *Candida* spp. and cryptococcal infections are the most prevalent mycoses in AIDS patients. Histoplasmosis is common among AIDS patients in the endemic area for that disease and coccidioidomycosis is frequent among the population where *C. immitis* is found. There have been only a few reports of AIDS (or other immunocompromised) patients with blastomycosis. The first account of this combination was made by Chiu et al. (1988). The only collective, comparative review was published by Pappas et al. (1992). Their series of 15 AIDS patients with blastomycosis reported that the disease was usually disseminated, survival was short and the central nervous system was frequently involved (Pappas et al. 1992). While only a limited number of such patients have been reported to date (Kitchen et al. 1989; Herd et al. 1990; Fraser et al. 1991; Harding 1991), Pappas et al. have reported that an increasing proportion of blastomycosis patients seen at their medical center (24 percent seen between 1978 and 1991) have underlying impairment of immunity (Pappas et al. 1993). Mortality rates in such patients are high and exceed 30 percent. Maintenance antimycotic therapy may be required for AIDS patients with blastomycosis as it is for those with cryptococcosis.

As with the other endemic mycoses, some AIDS patients with blastomycosis had not lived in an endemic area for several years. These findings support the case for subclinical infection with sequestration of a quiescent nidus of infection. Endogenous reactivation occurs when host defenses are compromised as in the case of these AIDS patients.

It is interesting to note that, in 1914, Stober commented that, in humans, host resistance must be substantially diminished for an infection with *B. dermatitidis* to occur (Stober 1914). The detailed clinical aspects of blastomycosis were recently reviewed (Causey and Campbell 1992; Pappas and Dismukes 2002).

Radiology

There are no diagnostic radiological features of blastomycosis. Pulmonary infiltrates, consolidation, cavities, miliary and intermediate nodules, and mass-like lesions have been reported, but the distribution of this pathology differs among studies (Pfister et al. 1966; Halvorsen et al. 1984; Sheflin et al. 1990; Brown et al. 1991). Although pathologists claim that pleural effusions are an uncommon finding postmortem (Schwarz and Salfelder 1977), some radiologists claim that 20 percent of their blastomycosis patients had signs (blunting of the

costophrenic angle) that were consistent with fluid (Sheflin et al. 1990).

The location of the pulmonary abnormalities also varied with the reports. One or both lungs may be affected. Bilateral disease is more common, although the abnormalities may occur in either the right or left lung. Upper or lower lobes may be involved but more often the disease is limited to the upper lobes.

Pathology

GROSS PATHOLOGY

The gross pathology of the dermal lesions in primary and secondary blastomycosis has been adequately characterized in the clinical description of the disease. The two types of lesions are distinct and an exposure history will support the diagnosis of primary cutaneous blastomycosis.

There is no characteristic gross appearance of organs with blastomycetic lesions. When the patient has had disseminated disease the lesions will vary with the extent of the pathology and the organs involved. The lungs are the most frequently affected organ in blastomycosis. Clinically, radiologically and grossly, the lung lesions frequently resemble carcinoma. Schwarz and Baum (1951) found that the lungs were usually heavy, i.e. 2000 g for both. The cut surface is gray with small pneumonic foci, but the typical cavities, usually seen in other fungal disease or tuberculosis, are not found (Schwarz and Baum 1951).

The bronchial tree may be ulcerated and is often filled with exudate which contains many organisms. Cavitary lesions are not common. Pleuritis is frequent but pleurisy is unusual. Calcified nodules, common in histoplasmosis, are not found and caseation of the lymph nodes is not common. The gross lesions of other organs most closely resemble a tumor upon inspection. Histological examination and culture are required to confirm the diagnosis. Yeast forms of *B. dermatitidis* have been found in blood vessels and their presence is evidence that fungemia does occur (Schwarz and Salfelder 1977).

HISTOPATHOLOGY

Histological stains

The universal histological stain in general use in the pathology laboratory is the hematoxylin and eosin (H&E) stain. This reagent is used on all diagnostic tissue sections. It will stain many, but not all, fungi. The advantage of H&E is its capability to reveal tissue structures and the inflammatory reaction as well as the invading fungus. *B. dermatitidis*, however, is sometimes difficult to visualize in tissue sections stained by this method.

There are three special stains commonly used for *B. dermatitidis* and other fungi. The special stains provide a sharp delineation of the fungus and demonstrate its typical characteristics. Gomori's methenamine–silver nitrate (GMS) stain outlines the fungal cell walls which are stained a deep black whereas the intracellular portions of the yeast cells are rose colored. The tissue background is light green, providing an effective contrast with the organism. This stain is especially useful for the inexperienced pathologist and when there is a paucity of organisms in the infected tissue. A combination of GMS and H&E has the advantages of both stains: readily visualized organisms and the opportunity to evaluate the host tissue reaction. With the periodic acid–Schiff (PAS) stain the fungus is red with a pink or light green background depending on the counterstain. It outlines *B. dermatitidis* distinctly and is preferred by some pathologists for the study of fungal histopathology. The Papanicolaou stain, commonly used in exfoliative cytology, also stains *B. dermatitidis* very well. The translucent cell wall is obvious whereas the cytoplasm is granular and stains a pale pink (Trumbull and Chesney 1981). The yeast forms can be readily visualized with ordinary cervical cytology screening procedures (Dyer et al. 1983).

The direct fluorescent antibody (DFA) test is a serological tool that is useful for the rapid and specific identification of certain fungi. It is specific for *B. dermatitidis*, when evaluated with the morphological characteristics of the suspect organism. DFA is not a stain, but a visible antigen–antibody reaction which fluoresces and outlines the fungus cell (Kaplan and Kaufman 1963). These reagents will stain only the yeast form and therefore this tool is most useful as an adjunct to histopathology. A fluorescence microscope and specific filters are required. Unfortunately, these reagents are not commercially available, so specimens must be sent to a reference laboratory that offers the desired analysis.

Nested polymerase chain reaction (PCR) has been investigated on tissue from dogs infected with *B. dermatitidis* (Bialek et al. 2003). Formalin-fixed, paraffin-embedded tissues were examined for evidence of this organism. PCR amplification of the gene encoding the unique *BAD1* adhesin was found to be as sensitive as, and even more specific than, PCR amplification of 18S rDNA for detection of *B. dermatitidis* in canine tissue. Neither was PCR crossreactivity seen in human tissue from biopsy proven cases of histoplasmosis

Morphology

Morphology is the key to the histological identification of *B. dermatitidis*. Individual cells or budding cells may be seen. The single bud with a wide base and a thick wall ('double contoured') is pathognomonic of blastomycosis. The fungus cells are 8–12 μm in diameter and round or globose in shape. Careful examination may reveal that the yeast cells contain several nuclei, with a retracted cytoplasm within the cell wall. The yeast cells may be free in the tissue or within giant cells. The inflammatory reaction is a mix of poly-

morphonuclear cells and a granulomatous reaction. Early lesions are usually suppurative with a polymorphonuclear infiltrate. As the inflammatory process proceeds, a granulomatous or mixed response with multinucleate giant cells appears in the lesion. The giant cells contain nuclei both in the centre and the periphery of the cell (Figure 8).

Size variation

The microscopist should be aware that both small and large forms of *B. dermatitidis* do occur. Small forms, 2–10 μm in diameter, have been described (Manwaring 1949; Tompkins and Schleifstein 1953; Tuttle et al. 1953; Schwarz and Salfelder 1977). These diminutive cells resemble those of the *capsulatum* variety of *H. capsulatum* in size, but they posses the characteristic broad base of *B. dermatitidis*. *H. capsulatum* yeast forms are usually elliptical and are more apt to be seen within mononuclear or polymorphonuclear leukocytes rather than giant cells. Large forms of *B. dermatitidis* have also been reported. Watts et al. (1990) described a case of pulmonary blastomycosis in which cells of *B. dermatitidis* as large as 40 μm in diameter were found in lung tissue. Walker et al. (2002) described culturally confirmed cutaneous lesions with yeast cells 20–40 μm in diameter. One of 10 wild strains of *B. dermatitidis* isolated from soil also produced large yeast forms. When recovered from experimentally infected mice, most cells from this isolate were 25–30 μm in diameter (Denton and Di Salvo 1964). Histologically, these aberrant forms have frequently been found mixed with yeast cells of normal size and morphology. In those instances, where cultures have been made, the yeast forms grew in the normal size range (W. Kaplan 1988, personal communication). It is interesting to note that Stober described small forms (diameter 3–5 μm) and large forms (diameter 25–30 μm) in 1914 (Stober 1914).

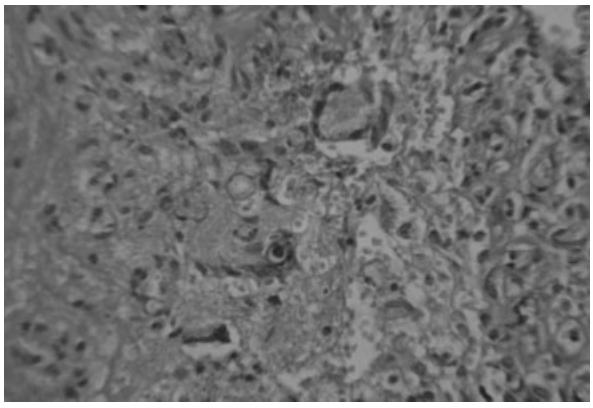

Figure 8 *A microscopic view of a tissue section with a bone lesion caused by* Blastomyces dermatitidis. *Note the giant cell containing nuclei and cells of the yeast form. As a result of the large size of the tissue-form of this organism, the yeast invoked a foreign body tissue reaction.*

Mycelial forms

Mycelial forms of *B. dermatitidis* have occasionally been seen in tissue (Hardin and Scott 1974; Kaufmann et al. 1979; Atkinson and McCurley 1983) and bronchial washings (Herd et al. 1990). The latter case was an AIDS patient, and the mixture of tissue and mycelial forms found in this patient was similar to that found in an AIDS patient with coccidioidomycosis. These hyphal forms of *B. dermatitidis* are usually short, septate, and hyaline, with occasional branches which resemble the pseudomycelium of *C. albicans*.

Skin

The common histological finding in cutaneous blastomycosis is pseudoepitheliomatous hyperplasia with squamous cell proliferation and acanthosis. Intraepithelial and dermal microabscesses with budding yeasts are seen. Giant cells may or may not be present and the organisms can be found within or outside the giant cells. In chronic cutaneous blastomycosis eosinophils may be seen.

Other organs

Abscesses with few or numerous organisms may be seen or the yeast-like cells may be dispersed in the lesion. The host inflammatory reaction may be both suppurative and granulomatous. As in the cutaneous lesions, the organisms are frequently found in giant cells. In bones, a granulomatous osteomyelitis is usually seen.

Caveat

For the inexperienced pathologist, it may be difficult to make a definitive diagnosis of *B. dermatitidis* if the typical morphological forms are not present in the tissue sections being examined. This occurs when there are only a few fungal cells present or when budding yeasts are not found. *B. dermatitidis* may then be difficult to distinguish from the *duboisii* variety of *H. capsulatum*, *C. immitis* (immature spherules), *P. brasiliensis* (look for multiple buds, thin walls, narrow attachment of daughter cells), or *C. neoformans* if a large capsule is not present (look for a capsule or use the mucicarmine stain which tints the smallest amount of the polysaccharide capsule). *Candida* spp., and sometimes *S. schenckii*, will appear as round cells. The DFA can resolve many of these problems if no typical forms are present. A comprehensive review of the pathology of blastomycosis can be found in Chandler and Watts (1992).

Host–pathogen interactions

DIMORPHISM AND VIRULENCE

Transition to a yeast form is a requirement for pathogenesis. Medoff et al. (1986) treated *H. capsulatum*

mycelia with the sulfhydryl inhibitor *p*-chloromercuriphenylsulfonic acid (PCMS), to prevent conversion to the yeast form, and showed that inoculation with this material no longer caused disease in a murine model of infection. His findings imply that yeast-form-specific factors are essential for pathogenicity of dimorphic fungi. To date, few form-specific genes have been identified in *B. dermatitidis* and other dimorphic fungi. One of the best studied in *B. dermatitidis* is *BAD1* (*Blastomyces* adhesin; formerly WI-1). A number of molecular and genetic tools applied to *B. dermatitidis* have aided the study of this yeast-form-specific virulence factor, as described below. Another yeast-form specific gene of *B. dermatitidis* is *bys 1* (*Blastomyces* yeast-specific), but its function is unknown (Burg and Smith 1994). α-Glucan is an additional differentially expressed product of *B. dermatitidis*. The cell wall glucan content of *B. dermatitidis* yeast is 95 percent α-glucan (Kanetsuna and Carbonell 1971), which is situated in the outer wall. By contrast, the proportion of α- and β-glucan is more evenly distributed in the cell walls of the mold. Hence, these polymers are differentially expressed in the yeast and mold forms of the fungus. In *B. dermatitidis*, as well as in *P. brasiliensis* and chemotype II strains of *H. capsulatum*, the loss of yeast cell wall α-(1,3)-glucan in genetically related variants correlates with the loss of virulence in animal and cell culture models of infection (Hogan et al. 1996).

TOOLS FOR GENETIC MANIPULATION OF *B. DERMATITIDIS*

Study of *B. dermatitidis* pathogenicity has benefited from the application of molecular biological tools (Brandhorst et al. 2002). High-voltage electric pulse was used first for introducing foreign DNA into *B. dermatitidis* (Hogan and Klein 1997). Transformation efficiency by electroporation is low, however (range, 1–42 c.f.u./μg transforming DNA). Where numerous transformants must be screened, a more efficient gene-transfer method is desirable. *Agrobacterium tumefaciens*-mediated gene transfer, developed originally for transformation of plant species, has been adapted for use with *B. dermatitidis* (Sullivan et al. 2002), and routinely generates transformants with a frequency of up to 10^3 per 10^7 per target yeast. Transforming DNA chiefly integrates into a single chromosomal locus. This method of DNA transfer thus offers the advantages of single-site integration, desirable for insertional mutagenesis, and a high yield of transformants.

The *Escherichia coli* hygromycin phosphotransferase gene (*hph*), coding for hygromycin B resistance, serves as the staple dominant marker for transformation. Chlorimuron ethyl resistance, encoded by the *sur* (sulfonylurea resistance) gene from *Magnaporthe grisea*, is another effective dominant selectable marker and has been useful in retransformation of previously manipulated, hygromycin-resistant strains. G418 resistance also has been employed, yielding three options for antibiotic selection-based transformation (Brandhorst et al. 2002). Auxotrophic strains of *B. dermatitidis* have become available recently, when strains with spontaneous and UV-induced mutations in the *ura5* gene for uracil production were isolated using 5-fluoro-orotic acid selection (Sullivan et al. 2002). Complementation of this auxotrophy offers more efficient selection than antibiotic resistance.

Homologous recombination takes place in *B. dermatitidis*, but its rate relative to the usual mode of illegitimate recombination is uncertain. To knock out the *BAD1* gene by homologous recombination, the *hph* selection marker was placed downstream of a truncated span of *BAD1* promoter. This strategy may have functioned as a promoter trap. Homologous replacements of *BAD1* represented about 1–2 percent of hygromycin B-resistant transformants (Brandhorst et al. 1999). Targeted knockout of genes, while attainable by more conventional techniques, may be enhanced by such a strategy. Reporters for studies of gene regulation have been developed for *B. dermatitidis*. β-Galactosidase activity can be measured in extracts of *B. dermatitidis* transformed with this reporter, and *BAD1*–β-galactosidase reporter fusions have been used to confirm that *BAD1* is transcriptionally regulated (Rooney et al. 2001). A β-glucuronidase reporter is also functional in *B. dermatitidis* (Brandhorst et al. 2002).

IMPORTANCE OF BAD1 IN PATHOGENESIS

Manipulation of the *BAD1* locus is an example of the application of new molecular genetic tools. *BAD1* was successfully deleted from *B. dermatitidis* strain ATCC 26199 by allelic replacement. The knockout strain had diminished capacity to bind macrophages and murine lung tissue, compared to the parent strain, and most importantly, was found to be attenuated in a murine model of blastomycosis (Brandhorst et al. 1999). Binding and virulence defects were rescued by re-expression of *BAD1* in trans in the knockout strain. The indispensable role of *BAD1* in pathogenesis was thus uncovered using the molecular genetic tools now available in *B. dermatitidis*.

Sequence analysis of the *BAD1* gene predicts a product consisting of a short amino-terminal region, a 24-amino acid repeat, present in 30 tandem copies within the core of the protein, and a carboxyl-terminal region that possesses homology to epidermal growth factor (Hogan et al. 1995). The C-terminal EGF domain is important for BAD1 localization on the yeast cell surface (Brandhorst et al. 2003). The tandem repeat of BAD1, which constitutes over 75 percent of the protein's primary structure, mediates binding of macrophage CR3 and CD14 receptors (Newman et al. 1995). BAD1 binding to phagocytes has also been found to modulate host immune responses. For example, BAD1

downregulates the production of tumor necrosis factor-alpha (TNF-α), which is normally stimulated in response to the infection, and critical for host defense (Finkel-Jimenez et al. 2001). A *BAD1* knockout strain evokes the production of TNF-α in vivo in an experimental model of infection and in vitro during co-culture with macrophages and neutrophils, whereas the isogenic, wild-type strain (and purified *BAD1*) curtails TNF-α production, promoting progressive infection. BAD1 modulates TNF-α production partly through inducing transforming growth factor-beta (TGF-β), which antagonizes phagocyte TNF-α responses (Finkel-Jimenez et al. 2002). Hence, in addition to promoting binding of the fungus to cells and tissue, BAD1 enhances pathogenicity by allowing *B. dermatitidis* to evade host immunity by modulating it in a manner that favors fungal survival over host survival.

BAD1 AND FORM TRANSITION

BAD1 is only found on the surface of the yeast form of *B. dermatitidis*, and not on the surfaces of hyphal filaments or conidia that make up the mold form (Rooney et al. 2001). BAD1 is not a prerequisite for the form transition to yeast. Strains from which BAD1 has been deleted undergo form transition in both directions with no hindrance. Given the established role of BAD1 in pathogenesis, these observations help explain how the thermally triggered form transition leads to establishment of a virulent state. Once conversion to yeast has begun, BAD1 rapidly accumulates on the surface of the organism. An analysis of yeast and mycelial morphotypes employing both Northern hybridization and reporter genes fused to the *BAD1* promoter has shown that the form-specific regulation of *BAD1* is tightly controlled at the level of transcription (Rooney et al. 2001). Hence, a virulence gene – *BAD1* – has proven to be under transcriptional control that is tied, either directly or indirectly, to the temperature-induced transition from mold to yeast.

Many African strains of *B. dermatitidis* are naturally devoid of BAD1, as they lack the gene for this protein (Klein et al. 1997). When the BAD1 coding region, under the control of its native promoter, was transferred into an African strain of *B. dermatitidis*, the heterologously expressed BAD1 retained form-specific expression and control at the level of transcription. The same phenomenon was observed when the *BAD1* gene was transferred into *H. capsulatum*, which also lacks a native *BAD1* locus, indicating that the form-specific mechanism of transcriptional control is conserved (Rooney et al. 2001). Sequence analysis of the upstream region of *BAD1* identified regions of homology with the promoter of the *H. capsulatum* yeast-form-specific gene *yps-3*. It seems likely that other, as yet undefined, yeast-form-specific genes may be controlled by the same transcriptional regulatory mechanism.

HOST DEFENSE MECHANISMS

Polymorphonuclear leukocytes (PMN) efficiently phagocytose and kill the conidia of *B. dermatitidis*. By contrast, Drutz and Frey (1985) demonstrated that PMNs do not ingest *B. dermatitidis* yeast cells. Instead they surround and attach to extracellular yeasts. The lack of phagocytosis is attributed to the size of the yeast cells. PMN killing of conidia and yeast is mediated by oxidative mechanisms. Killing of the yeast is thought to involve an extracellular process, whereby PMNs attach to the yeast and empty granule contents in the extracellular space (Diamond and Krzesicki 1978). Brummer and Stevens (1982) have reported that PMNs augment growth of yeast in vivo and in vitro, rather than kill the fungus, fueling controversy about the role of PMNs in host defense.

Alveolar macrophages readily ingest conidia, but have difficulty both ingesting and killing yeast. Peripheral monocytes and especially monocyte-derived macrophages ingest and kill conidia and yeast more efficiently. Macrophage functions are enhanced with cells from immunized patients (Bradsher et al. 1985). Killing of yeast cells by interferon-gamma (IFN-γ)-activated macrophages does not depend on products of the oxidative burst (Brummer and Stevens 1987).

Bradsher described an in vitro test to quantify cell-mediated immunity in patients with blastomycosis (Bradsher and Alford 1981). The *Blastomyces* alkali-soluble water-soluble (ASWS) antigen developed by Cox (Cox and Larsh 1974) was used to measure lymphocyte migration inhibition and lymphocyte transformation. An outbreak of blastomycosis in which 48 patients were identified with acute pulmonary blastomycosis provided an opportunity to evaluate this assay in humans (Klein et al. 1990). Most patients developed specific cellular immunity between 3 months and 21 months after exposure to *B. dermatitidis*. The assay may offer an epidemiologic tool to elucidate the geographical distribution of blastomycosis. A detailed discussion of the immunology of *B. dermatitidis* has been published by Klein (1992).

As early as 1914, results of autogenous vaccines were reported. Stober described three patients (Stober 1914). One patient did well and two improved for a short period of time, then relapsed and died. There has been no recent investigation into the immunization of humans. Mice were shown to be protected against a lethal challenge with *B. dermatitidis* yeast cells by immunization (recovery from nonlethal subcutaneous infection) (Morozumi et al. 1982). Protection was mediated by cells and not serum, supporting the previous studies by Cozad and Chang (1980), which established that cellular immunity mediates protection against *B. dermatitidis*. More recently, Wuthrich et al. (2000) described a genetically engineered attenuated vaccine strain of *B. dermatitidis* that harbors a targeted deletion

of *BAD1*. The vaccine confers sterilizing immunity against infection with isogenic and nonisogenic strains in a murine model, and has allowed investigation of the cellular molecular mechanisms of acquired immunity in the murine system. As in prior work, T cells rather than B cells are largely responsible for vaccine immunity, particularly $CD4^+$ T cells. Type 1 cytokines including IFN-γ, TNF-α, and granulocyte-macrophate colony-stimulating factor (GM-CSF) are instrumental in immunity mediated by these cells in normal hosts (Wuthrich et al. 2002). There is sufficient redundancy in immune-deficient hosts so that an absence of one or more of these products can be offset by a compensatory response in one of the others. For example, IFN-γ deficiency can be compensated by TNF-α, and conversely, TNF-α deficiency can be compensated by GM-CSF (Wuthrich et al. 2002). This theme has been extended to studies in $CD4^+$ T-cell-deficient hosts (Wuthrich et al. 2003), where $CD8^+$ T cells subsume the role of T-cell help, producing the type 1 cytokines needed for host defense and sterilizing immunity against *B. dermatitidis* (or *H. capsulatum*). These studies raise the prospect that engineered vaccines can protect against infection with *B. dermatitidis* or related fungi, possibly even in immune-deficient hosts (Casadevall and Pirofski 2003).

LABORATORY DIAGNOSIS

The diagnosis of blastomycosis in a patient frequently requires a combination of several techniques. The clinical signs and symptoms are nonspecific. Some commercial serological tests lack specificity and most lack sensitivity. The histological picture may not be clear as a result of the morphological similarity with other mycotic agents and nonmycotic artifacts. A presumptive diagnosis can frequently be made by integrating patient history, the clinical symptoms, a wet mount examination, and serology. The only absolute laboratory diagnostic criterion for blastomycosis is the isolation and identification of *B. dermatitidis*.

As the fungal etiologic agent is not always apparent on clinical presentation of the patient, universal methods for fungus culture are performed if a mycotic disease is suspected. The techniques for the isolation and identification of mycotic agents are described in detail in Laboratory diagnosis. Table 1 describes the appropriate clinical material to be selected for the isolation of *B. dermatitidis*. The application to blastomycosis will be described briefly.

Direct examination

The observation of yeast cells in an adequate clinical sample is a quick way to establish a preliminary diagnosis. However, isolation and culture are essential to confirm the diagnosis. The specimens to be submitted to the laboratory depend on the manifestations of the disease: skin scrapings or pus from skin lesions; sputum in cases of pulmonary disease; and biopsy tissue from any lesion. Urine, even in the absence of urinary tract symptoms, is frequently a good source of the organism in males. The yeasts are most probably liberated from an infected prostate gland. Although hematogenous dissemination is common in blastomycosis, blood cultures have only rarely yielded this fungus (Musial et al. 1987).

Direct microscopic examination of the clinical material can readily be performed. A typical cutaneous lesion shows central healing with microabscesses at the periphery. A pus specimen may be obtained by nicking the top of a microabscess with a scalpel. The exuded purulent material is mixed in a drop of 20 percent KOH on a microscope slide. A coverslip is applied and the slide is heated gently to clear the tissue and purulent material without damage to the fungus. The wet mount is then examined under the microscope. *B. dermatitidis* appears as a round yeast cell with double wall and often with a single bud. Usually the cells are uniform in size, 8–12 μm, readily seen in pus or infected tissue with KOH. The apparent double wall and broad-based bud are characteristic. Bud scars are sometimes seen at the side of the juncture of the mother and daughter cells. Both cells are frequently the same size and appear as a figure-of-eight (see Figure 5).

Culture

The preferred medium for the isolation of *B. dermatitidis* is Emmons' modification of SGA. The modification includes the addition of antibiotics to inhibit bacterial contamination, a decrease in glucose from 4.0 percent to 2.0 percent and a final pH of 6.9. The reduced sugar content is more favorable for the recovery of *B. dermatitidis*. Samples submitted for culture are incubated at both 35–37°C and 25–30°C. All cultures should be held 4–6 weeks before discarding as negative.

PRESUMPTIVE DIAGNOSIS

A presumptive identification of *B. dermatitidis* is based on the colonial and microscopic morphology as described above and the conversion of the isolated form to the converse. The dimorphic attribute applies to only a few human pathogens and the structures of one form or the other are sufficiently distinct to the experienced mycologist to allow the identification of the isolate. In recent years several means of verifying the identity of *B. dermatitidis* have been developed: exoantigen, DNA probe, and DFA.

EXOANTIGEN

A simple, specific, and sensitive test to identify the mycelial form of dimorphic fungi is the exoantigen test

(Kaufman et al. 1983). This is a double immunodiffusion reaction in agar performed by using an aqueous extract of a 7–10-day-old mycelial culture as the unknown antigen. This unknown antigen solution is precipitated against a known, standardized antiserum. A sharp, clear precipitin band of identity is formed where the antigen and the homologous antiserum meet. This test, with the proper antiserum, is 100 percent specific for *B. dermatitidis* and can also be applied to the identification of other dimorphic fungi. It is interesting that nonviable mycelial cultures of *B. dermatitidis* can be identified by this method (Di Salvo and Wooten 1982) and *B. dermatitidis* can be specifically identified even when the extracted culture is contaminated (Di Salvo et al. 1981).

DIRECT FLUORESCENT ANTIBODY

The direct fluorescent antibody (DFA) test for *B. dermatitidis* was developed by Kaplan and Kaufman (1963). There are several advantages of this rapid procedure to identify yeast forms of the fungus. The technique may be applied to tissue sections or to a yeast-form culture. Tissue, suspected of being malignant, is often removed at surgery and placed in formalin. Later, when the possibility of a fungous infection is being considered, clinical material for culture is not available. If the organisms in the tissue are not typical because of unusual shapes or size, the morphology may not be sufficient for a definitive diagnosis. Where morphology among yeasts can be very confusing, DFA is specific. When applied to unknown yeast organisms, DFA will fluoresce positive as soon as growth is visible. The stain will identify *B. dermatitidis* whether or not the organisms are viable.

NUCLEIC ACID PROBES

A simplified test using nucleic acid probes has recently been developed for the identification of *B. dermatitidis* cultures. The probes may be applied to either the mycelial or yeast forms of the organism. The single-stranded DNA probe is combined with a chemiluminescence label for detection. If the unknown organism is *B. dermatitidis*, the DNA probe will hybridize with the RNA of the target organism. The labelled DNA/RNA hybrid is then detected for identification of the fungus. In three evaluations of the nucleic acid probe, the sensitivity ranged between 87.8 percent and 100 percent. Two studies reported 100 percent specificity (Scalarone et al. 1992; Stockman et al. 1993). The third evaluation tested 17 strains of *P. brasiliensis*, a morphologically similar dimorphic fungus (Padhye et al. 1994). These investigators found that 10 of the 17 *P. brasiliensis* strains hybridized with the *B. dermatitidis* probe. This crossreaction is not an obstacle if the morphology is distinctive for the suspected organism. The commercially available reagents are expensive, but the test requires less than 2 hours to confirm the identity of the isolate. Any rapid means of identification is welcome by mycologists because the traditional methods required to isolate and identify dimorphic fungi require 4–6 weeks. In the future, the nested PCR assay for detecting *B. dermatitidis BAD1* sequences, developed by Bialek et al. (2003), may fulfill this criterion.

A comprehensive discussion of specific culture methods for each type of clinical material has been published (Goodman 1992). Detailed diagnostic laboratory procedures for the microbiologist are described in that publication.

Serodiagnosis

As fungal pulmonary infections cannot be etiologically classified clinically, the serological tests for fungal infections are requested, and performed, as a group. Most diagnostic laboratories in the USA perform fungal serology as a battery for the endemic mycoses blastomycosis, histoplasmosis, and coccidioidomycosis.

There are two serological tests in general use which detect antibodies to *B. dermatitidis* and are used for the diagnosis of blastomycosis: the complement fixation (CF) test and the immunodiffusion (ID) precipitin test. The CF test usually requires 2–3 months for antibody to be detected. Both the sensitivity and the specificity of the CF test are poor. However, the results are quantitative and may aid in evaluating the progression of disease or efficacy of therapy. The ID or precipitin test may be positive in up to 80 percent of the patients with blastomycosis, 2–3 weeks after the onset of symptoms, and its specificity is close to 100 percent. A positive test indicates recent or active disease. The enzyme immunoassay (EIA) test is a more recent development in the diagnosis of blastomycosis. In one small trial of a commercial diagnostic kit, the procedure was shown to have a sensitivity of 100 percent and a specificity of 85.6 percent (Sekhon et al. 1995).

An outbreak of blastomycosis among a group of 95 individuals exposed to a point source of *B. dermatitidis* provided an opportunity to study the serology of this disease. A comparison of the CF, ID, and EIA tests on 47 patients meeting the case definition was reported (Klein et al. 1987b). They found these three tests to have a sensitivity of 9, 28, and 77 percent, respectively, and a specificity of 100, 100, and 92 percent. The low sensitivity in this study may be the result of the number of asymptomatic or mild cases of blastomycosis identified in this cohort. The EIA testing was performed at the Centers for Disease Control and Prevention (CDC) using their reagents, not the commercially available kit. As the day of exposure was known with certainty, which is not usually the case in blastomycosis, the time required for the development of antibody could be determined reliably. The conclusion of this study was that, in this instance, the EIA antibody was detected as

early as 13 days and peaked at 50–70 days after the onset of symptoms. The ID antibody peaked at the same time but did not appear earlier. Therapy shortened the antibody window, but the three tests did not appear to have any prognostic value. A report by Kaufman (1992) specifically described the present immunodiagnosis of blastomycosis in greater detail.

A noncommercial radioimmunoassay has been reported that incorporated BAD1, which is a target of both antibody and T-cell responses (Klein and Jones 1990). Sensitivity and specificity were 85 and 97 percent, respectively, in 68 patients with blastomycosis, and 73 patients with other systemic mycoses. Follow-up studies demonstrated that BAD1 tandem repeats are the target of the antibody response in patients and that these sequences are present in the A antigen of *B. dermatitidis*. BAD1 and A antigen of *B. dermatitidis* are thus similar antigens, if not the same, although detailed biochemical studies of the antigens demonstrated that carbohydrate on A antigen (lacking on BAD1) accounts for crossreactivity with sera from histoplasmosis patients or rabbit histoplasmosis immune sera (Klein and Jones 1994).

TREATMENT

Not all patients with blastomycosis require antifungal therapy. It is customary to observe the patient with suspected mild pulmonary blastomycosis while the cultures are pending. In many patients, the pneumonia will clear spontaneously. If progression of the disease is obvious, an antimycotic agent should be considered. There are two major classes of antimycotic agents used for blastomycosis: the polyenes and azoles.

The polyene amphotericin B, introduced in the 1960s, is still considered the gold standard of therapy for blastomycosis and other systemic mycoses. This drug must be administered intravenously for several weeks. The initiation of therapy requires hospitalization, close observation of the patient, and monitoring of renal function. Amphotericin B has significant side effects in many patients, but relapses are few after an adequate course of therapy (about 2 g). The mechanism of action of this agent is believed to be an alteration of the permeability of the cell membrane of the yeast cells which allows essential constituents of the fungus to leak from the cell with subsequent death of the fungus. It is still considered the drug of choice by many infectious disease physicians, particularly in patients with severe disease or underlying impairments of immunity.

The azoles cause fungistasis by blocking the enzyme which converts lanosterol to 14-demethyllanosterol. This biochemical sequence is the forerunner of ergosterol synthesis. The triazole, itraconazole, is presently the drug of choice for mild cases of blastomycosis. This oral medication can be administered on an outpatient basis and is less toxic than amphotericin B. Some physicians still debate whether antimycotic therapy is necessary after surgical excision of pulmonary lesions (Edson and Keys 1981). More conservative clinicians tend to provide the additional antibiotic therapy. For immunocompromised patients, particularly those with AIDS, or in life-threatening infection, amphotericin B is still the drug of choice. A detailed account of the therapy of blastomycosis with various antimycotic agents has recently been published by Bradsher et al. (2003). Additional information on antifungal therapy is presented in Principles of antifungal therapy.

The recognition of patients infected with blastomycosis requires a detailed patient history and knowledge of the ecology and epidemiology of *B. dermatitidis*.

Coccidioidomycosis

DEMOSTHENES PAPPAGIANIS

Etiologic agent	1	Laboratory diagnosis	12
Host response	6	References	15

Coccidioides immitis (a second species, *Coccidioides posadasii* sp.nov., has been proposed by Fisher et al. 2002), is a soil-inhabiting fungus which, usually following inhalation, causes coccidioidomycosis. It usually occurs naturally only in certain areas of the western hemisphere. The disease, in its various manifestations, has also been called coccidioidal granuloma, San Joaquin fever, valley fever, and desert rheumatism. As a result of its persistent geographical distribution, coccidioidomycosis is an 'endemic systemic mycosis.' *C. immitis* undergoes a morphological change from its hyphal/arthroconidial form in nature, or in the usual laboratory culture, to a spherule-endospore form in vivo. It is thus grouped with the dimorphic systemic pathogenic fungi.

Recent reviews of coccidioidomycosis and coccidioides are provided in *Seminars in Respiratory Infections* (Ampel 2001) and by Cole et al. (2004).

Coccidioides species have been included as a 'select agent' of bioterrorism.

ETIOLOGIC AGENT

History

During the nineteenth century, physicians in the central valleys of California described febrile maladies related to disturbance of the soil, which probably included coccidioidomycosis (Thompson 1969). The first definitive written word on the disease emerged in 1892 when Posadas, in Buenos Aires, reported on the disease in an Argentinian soldier. The disease had begun some 4 years earlier, with its first manifestations being cutaneous involvement; a physician, Dr Bengolea, described it as 'mycosis fungoides,' a neoplastic disease which involves the skin, but it became evident that this was a progressive, systemic, and altogether different disease. Posadas had noted microscopically an organism that resembled a protozoan, belonging to the group referred to as coccidia that are characterized by a cyst containing endocystic cells. Two years after the initial report by Posadas, a second case was reported, originating in California (Rixford 1894). In fact, in the next several decades this was the site of occurrence and recognition of most of the cases.

As a result of its resemblance to the protozoan coccidia, the organism was subsequently named *Coccidioides immitis* (coccidia-like, *im*, not; *mitis*, mild). [Interestingly, no additional case was recognized in Argentina until 35 years after Posadas' report (Negroni 1967)]. The fungal nature of the organism was unrecognized until 1900 at which time a filamentous mold, believed for several years to have been a contaminant of cultures obtained from patients' tissues and exudates, was shown by inoculation of laboratory animals to change its morphological form into one resembling a protozoan (Ophüls and Moffitt 1900). This provided proof of the diphasic fungal nature of *C. immitis*.

Significant migration of individuals into the endemic areas of the southwestern USA occurred in the 1930s, as a result of catastrophic ecological and economic changes elsewhere in the USA. With the start of World War II in the early 1940s, military troops were also brought into endemic areas. These two groups of largely susceptible individuals permitted refinement of the knowledge about coccidioidomycosis (Smith et al. 1946a). In 1956, specific antifungal therapy in the form of amphotericin B was introduced for the treatment of coccidioidomycosis

(Fiese 1957). The azoles, introduced in the 1980s, significantly altered the approach to treatment.

Mycology

C. immitis Rixford and Gilchrist, 1896, is diphasic and polymorphic (Figure 1). The hyphal arthroconidial form is the saprophytic or saprobic form, found in nature and the usual laboratory cultures, and infrequently in tissues of the infected host (arthroconidia were formerly referred to as arthrospores). Airborne arthroconidia are inhaled and convert to the spherule-endospore ('parasitic') phase in the infected mammalian host. Special cultural conditions permit the production of the spherule-endospore phase in vitro (Converse 1955). The taxonomic placement of *C. immitis* has customarily been in the Fungi Imperfecti (Deuteromycotina) owing to an absence of a demonstrable conventional sexual conjugational stage. However, Burt et al. (1996) have described 'cryptic sex' (which may resemble parasexuality) as providing a means of exchanging genetic information. There are variations in the phenotype of the mycelial phase but not the spherule-endospore phase. Several features have, however, indicated that coccidioides probably fits in the division Ascomycotina (Ascomycetes), family *Onygenaceae*, and order Onygenales (Currah 1985): the hyphae are septate and have septal pores close to structures that resemble Woronin bodies; thallic arthroconidia are produced from specialized hyphae (i.e. whole hyphal cells become thick walled spore-like structures) which alternate with empty, degenerate 'disjunctor' cells (Sigler and Carmichael 1976) (Figures 1 and 2). Four pairs of chromosomes are reportedly present.

The percentage of guanine–cytosine (49.1–49.61 percent) was similar in the spherule and hyphal forms of three strains of *C. immitis* [compared with 47.3 percent and 48 percent in *Histoplasma capsulatum* and *Blastomyces dermatitidis*, respectively, both of which are ascomycetes (Pappagianis et al. 1985)]; based on homology/relatedness studies of the 18S ribosomal gene, *C. immitis* was shown to be closely related to *H. capsulatum* and *B. dermatitidis* (as well as *Trichophyton rubrum*), providing affirmation of taxonomic affiliation with ascomycetes (Bowman et al. 1992). The DNA studied by restriction enzyme analysis allowed separation of *C. immitis* into two groups, I and II (Zimmermann et al. 1994). Fisher et al. (2002) concluded that group I corresponded to a new species, *Coccidioides posadasii* ('non-California') and group II, *C. immitis*

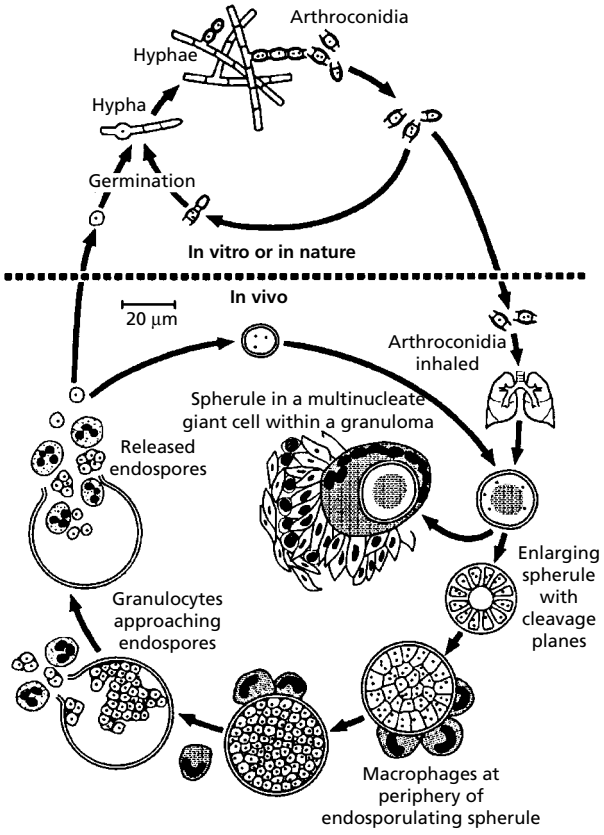

Figure 1 *Diagram illustrating the morphological forms of* Coccidioides immitis *in its saprobic form and its 'parasitic' form in vivo. The spherule/endospore form is depicted as evolving after inhalation of the arthroconidia, and the usual cellular reaction to the in vivo forms. (Adapted from Forbus and Bestebreurtje (1946) and others)*

Figure 2 *Chains of arthroconidia, some of which are separated by 'disjunctor' cells which undergo degeneration, first of the cytoplasm and later of the nuclei and cell wall.*

('California') species. There is no evidence that disease or its laboratory diagnosis associated with *C. immitis* or *C. posadasii* differs, or that response to therapy differs; and epidemiologic and experimental data indicate that immunity to these putative species is cross-protective (Pappagianis 1999).

The vegetative hyphal form can grow on a variety of media, ranging from those with sparse organic substrates (ammonium acetate suffices as a source of carbon and nitrogen) to the usual rich clinical laboratory culture media: blood agar, Sabouraud's, etc. On suitable media (e.g. 1 percent glucose/0.5 percent yeast extract/2 percent agar) arthroconidia are formed in 5–7 days at 34–37°C. These arthroconidia, usually 2–4×5–6 μm can be barrel-shaped, cylindrical, or oval and, when terminal on a hypha, they can be bullet-shaped. They form in the chain of cells of specialized hyphae developed from short hyphae 1–2 μm in diameter that are borne laterally on vegetative hyphae (2–4 μm in diameter). The arthroconidia, usually multinucleate and having a very refractile inner and outer wall, alternate with degenerating ('disjunctor') cells which share only the outer wall with adjacent arthroconidia (Huppert et al. 1982) (Figures 1 and 2). This thinner wall readily fractures, leading to disarticulation and, in appropriate currents of air, dispersion of individual or short chains of arthroconidia. When deposited on a suitable (nonviable) substrate with adequate moisture, the arthroconidia will germinate unilaterally or bilaterally to give rise to hyphae which, in turn, can produce arthroconidia. These airborne arthroconidia are highly infectious and it is necessary to be constantly aware of the potential infectious hazard to laboratory workers handling cultures, particularly from cultures more than 3 days old.

When the arthroconidia reach the airways of a human or other species (or are injected parenterally), and in the presence of host inflammatory cells (Baker and Braude 1956) and increased concentrations of CO_2 (Lones and Peacock 1960), the arthroconidia shed an outer wall layer and all but one nucleus, then become round and enlarge to produce a spherule. Nuclear division is followed by formation of cleavage planes of cell wall material which originates in the peripheral cell wall. It is likely that formation of the larger spherule from the smaller endospore involves several coordinated enzyme activities involved in the synthesis and breakdown of cell wall substances: synthases of chitin, glucan, mannan; lysis by chitinase, chitobiase, glucanase, mannosidase and proteases. In about 48 hours in vivo, the progressive growth and segmentation yield a mature spherule 20–150 μm in diameter with variable numbers, from a few to hundreds, of endospores 2–4 μm in diameter (Figure 3). These endospores can be released from the mature spherule, although the mechanism of release is uncertain but may involve proteases (Resnick et al. 1987; Yuan and Cole 1987), glucosidase (glucanase) (Kruse and Cole 1992) and chitinase (Johnson and Pappagianis 1992); these act upon the spherule wall and its internal projection around the endospores (Figure 4). The chitinase, and possibly also the glucanase and a protease, are important antigens in the induction of antibodies that have a significant role to play in the serodiagnosis of coccidioidomycosis (see section on Immunoserology, below). The released endospores enlarge in vivo and produce endosporulating spherules, which, in turn, can release another generation of endospores; in this way the pathogenic events continue. It is possible to demonstrate a similar formation of endosporulating spherules from an inoculum of arthroconidia or endospores in a synthetic medium (Converse 1955; Levine et al. 1960).

The metabolic activities have been summarized (Pappagianis 1988b). Expression of certain genes and their ultimate protein products (e.g. enzymes such as aldehyde reductase) can be specifically associated with the morphological (i.e. parasitic) spherule-endospore phase (Delgado et al. 2004). Some coccidioidal enzymes have been cloned and expressed by recombinant technology, e.g. chitinase (Zimmermann et al. 1996) and aspartyl protease (Johnson et al. 2000). *C. immitis* is catalase positive in both hyphal and spherule/endospore forms; it grows aerobically and readily uses glucose and other carbohydrates as carbon sources. Under anaerobic conditions, however, some metabolism can be carried out, and spherules produce more CO_2 than is produced by hyphae (Lones and Peacock 1960). The arthroconidia and hyphae can carry out endogenous respiration for many hours in the absence of an added carbon source. Both hyphae and spherules contain enzymes of the tricarboxylate cycle with the exception of α-ketoglutaric dehydrogenase. Isocitric lyase and malate synthase were, however, found in the hyphal form, suggesting that the glyoxylate bypass (conservative metabolism of fatty acids) can be utilized in the absence of 2-oxoglutaric dehydrogenase (Lones 1967). Endospores, but not spherules, use malate as a carbon source.

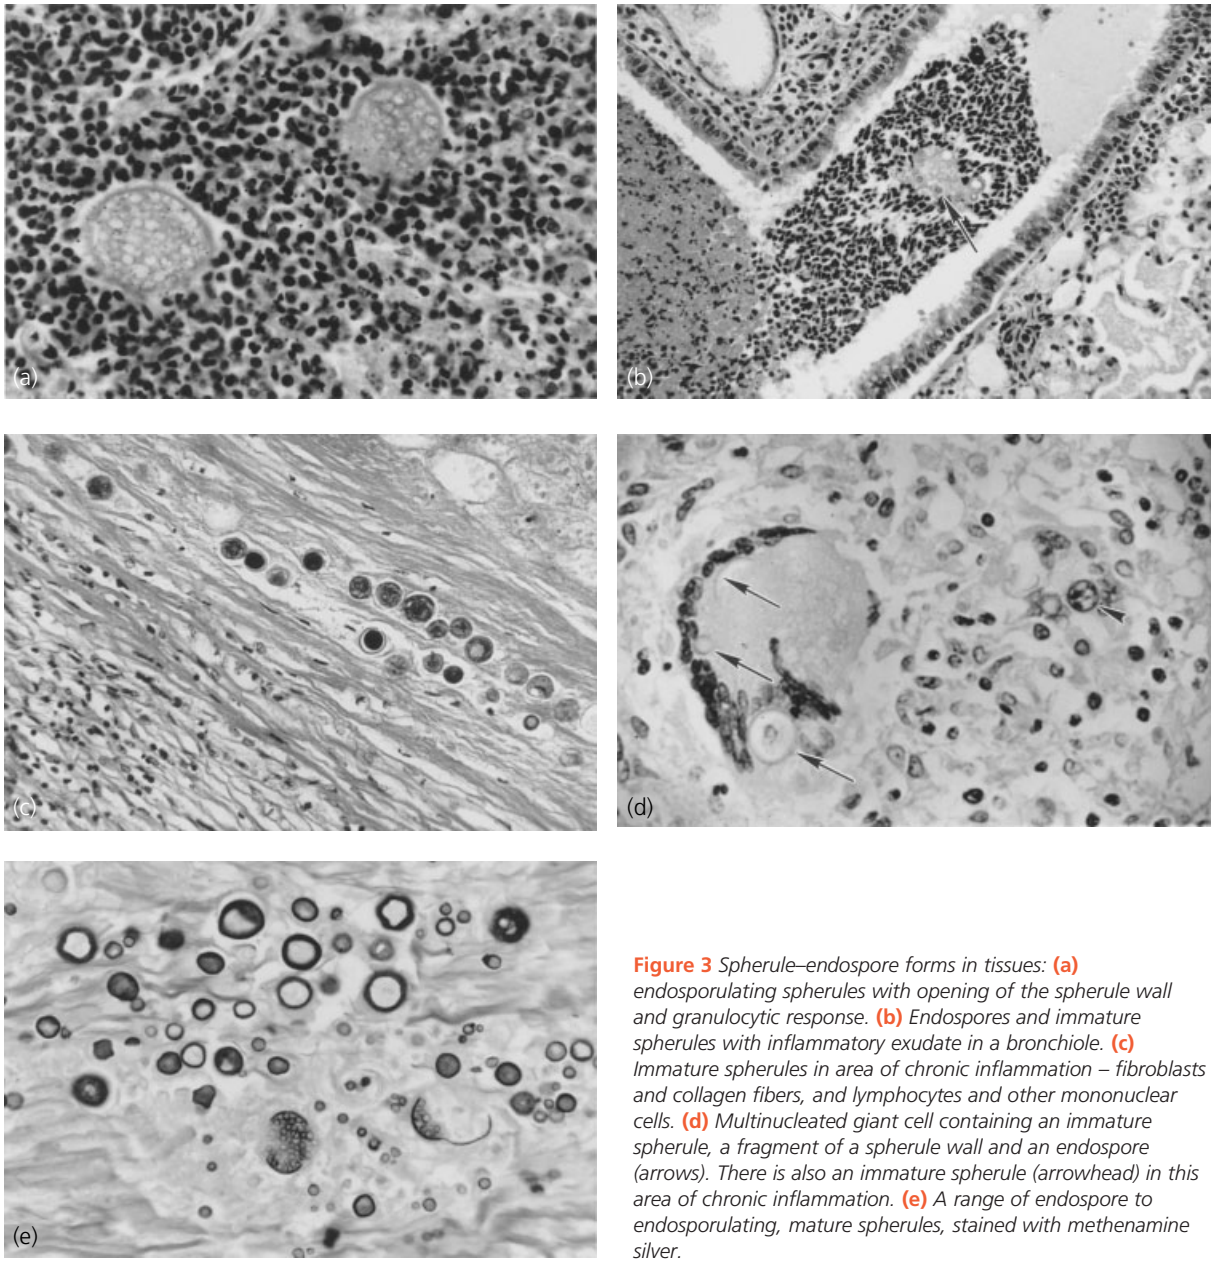

Figure 3 *Spherule–endospore forms in tissues:* **(a)** *endosporulating spherules with opening of the spherule wall and granulocytic response.* **(b)** *Endospores and immature spherules with inflammatory exudate in a bronchiole.* **(c)** *Immature spherules in area of chronic inflammation – fibroblasts and collagen fibers, and lymphocytes and other mononuclear cells.* **(d)** *Multinucleated giant cell containing an immature spherule, a fragment of a spherule wall and an endospore (arrows). There is also an immature spherule (arrowhead) in this area of chronic inflammation.* **(e)** *A range of endospore to endosporulating, mature spherules, stained with methenamine silver.*

The hyphae can utilize starch or xylose but the spherule/endospore form does not. Ammonium, nitrate, urea, acetamide, and several amino acids can be utilized as sources of nitrogen.

Ecology/epidemiology/geographic distribution

These aspects have been reviewed (Pappagianis 1988b). Coccidioidomycosis occurs primarily in arid and semi-arid areas of the western hemisphere where *C. immitis* lives in the soil, on the surface, and to a depth of 30 cm (Egeberg and Ely 1956). In the hottest periods of the year the soil temperature at the surface and to a depth of 1 cm can reach 60°C, which is lethal to *C. immitis* within minutes. Disturbance of the soil, with the creation of dust by winds or excavation or earthquakes (Schneider et al. 1997) throws arthroconidia up into the air. These conidia are hydrophobic and have a greater buoyancy with slower settling in air than would be expected for their size, ~2×5 μm. This allows them to be airborne for up to hundreds of kilometers. Such conidia-laden dust, which leads to infection, is most likely to occur in the hot dry seasons when the soil has become low in moisture.

The relative confinement of *C. immitis* to specific geographic areas, which has no precise explanation, makes coccidioidomycosis an 'endemic mycosis.' The

Figure 5 *Geographical distribution of* Coccidioides immitis *sites where coccidioidomycosis is usually acquired. (From Pappagianis (1980) with permission)*

regions fall between 40° North 120° West (Northern California) and 40° South 65° West (Argentina), and include the southwestern USA, California, Arizona, New Mexico, Texas, and small areas of Nevada and Utah, southern and northeastern (Petersen et al. 2004); Mexico; Honduras; Guatemala; Colombia; Venezuela; Paraguay; Argentina and, recently recognized, Brazil (state of Piaui). The name 'San Joaquin fever' or 'valley fever' is derived from a central region of California in which the disease is highly endemic (Figure 5).

Many, but not all, of the regions where the fungus is found conform to a bioclimatic area referred to as the Lower Sonoran Life Zone (Maddy 1957). *C. immitis* exists in areas that have relatively low annual rainfall (12.5–50 cm), hot summers (e.g. as in Phoenix, Arizona, a mean temperature 26–32°C) and relatively mild winters, though there is occasional snow at some elevations (900–1000 meters) where *C. immitis* is found. The soil is often sandy and alkaline (Swatek 1970). During the hot, dry season the soil has a high concentration of mineral salts which is better tolerated by *C. immitis* than by other microorganisms in the soil. Despite its survival in hot, dry, desert-like areas, where the relative humidity is usually no lower than 20 percent, it does not survive well at lower, e.g. 10 percent, relative humidity.

Rainfall has two influences: first, rain wets the soil, diminishing the airborne dust and fungal conidia, thereby reducing infections (Smith et al. 1946a); second, rainfall moistening the soil and *C. immitis* contained therein leads to germination of the fungal arthroconida; this supports a new round of vegetative growth, producing another crop of the infectious arthroconidia. Roughly, the higher the rainfall, the greater the number of cases of the infection that present in the succeeding hot, dry season (Pappagianis 1994). Although there is a greater risk of infection associated with soil-disturbing occupations, overall more cases are observed in persons not occupationally exposed, conforming to the easy movement of airborne arthroconidia.

Increased travel or immigration has led to increased numbers of cases among those entering the endemic areas (Ampel et al. 1998; Pappagianis 1994). Such cases have been observed in Europeans, Canadians, and Asians who have briefly visited the endemic western hemisphere, and in those who live elsewhere in countries with endemic *C. immitis* but who visit the endemic areas. A few infections have occurred in people who have never visited the endemic areas, but who have received or been exposed to exported products from these areas (Symmers 1967).

In addition to humans, a variety of other species have been infected with *C. immitis* (Table 1). There is a wide range of responses among animals in which infections have been recognized: cattle, sheep, and swine appear to be resistant to progressive forms of the disease; they are often infected and have mediastinal lymph node involvement while remaining clinically healthy. On the other hand, domestic horses

and llamas often have severe disease (Ziemer et al. 1992), though recently subclinical infections have been recognized in some domestic horses (Higgins et al. 2004). Przewalski (non-domesticated) horses have been recognized as having severe infections (Terio et al. 2003). Primates and monkeys have generally had severe disease, although arrest of the disease with antifungal therapy has been achieved. Domestic dogs appear to have disease patterns – mild to severe dissemination, especially involving the osteoarticular tissues – as seen in humans. Marine mammals (sea otters, sea lions, and recently a dolphin) which reside in the Pacific Ocean or its bays, are unique among these hosts. How they are infected is uncertain though the arthroconidia can travel long distances in the air, and their buoyancy and hydrophobicity could lead to their flotation on sea water and aerosolization by wind and/or wave action.

HOST RESPONSE

Clinical forms

Infection with *C. immitis* usually follows inhalation of the arthroconidia. Rarely, traumatic introduction of the organism into the skin leads to infection and disease (Wilson et al. 1953). In both instances, the regional lymph nodes are often involved: hilar in pulmonary infection, and inguinal in infection of the lower extremities. (Human-to-human transmission of *C. immitis* ordinarily does not occur, but has followed transplantation of organs from individuals with coccidioidomycosis

who served as donors (Tripathy et al. 2002; Wright et al. 2003.)

It is estimated that some 60 percent of individuals infected by the respiratory route are asymptomatic or have such a mild illness that medical attention is not sought (Figure 6). Their exposure to *C. immitis* is diagnosed from the presence of a positive skin test, or from detection of a chronic pulmonary residual lesion, 'coccidioidoma' or cavity, detected incidentally in a chest radiograph. Occasionally a previously healthy individual may present with hemoptysis or other complaint that can be referred to a cavity.

Of the 40 percent who develop symptoms, most will have an acute febrile illness beginning 7–28 days (average 10–16 days) after exposure to the organism. The clinical presentation has been reviewed in the literature (Galgiani 1993). Chest pain, often pleuritic and sometimes severe, occurs in 75 percent. The following symptoms occur in descending order: cough, fever, malaise, rash, sore throat, headache, arthralgia and/or myalgia. Anorexia, weight loss, and night sweats are encountered in some patients. These signs and symptoms resemble those of many other diseases and have led to designation of coccidioidomycosis as 'flu-like.'

The acute-stage pulmonary lesions, detected by chest radiograph, are also similar to those found in other diseases: small or large single or multiple infiltrates (the latter can resemble metastatic carcinoma); hilar and/or mediastinal adenopathy; transient cavity, pleural, or pleuropericardial effusions; miliary or reticulonodular lesions (each of which is prognostically unfavorable).

Various rashes occur, but erythema nodosum and erythema multiforme are most commonly seen (Quimby et al. 1992).

Of the 40 percent with symptomatic infections, most will recover completely. These patients are immune to exogenous reinfection as are those individuals who have incurred asymptomatic infections. About 10 percent of these patients will, however, be left with a pulmonary residual nodule or cavity, usually detected several months or years later. Infrequently, a chronic progressive fibrocavitary disease resembling apical tuberculosis or histoplasmosis capsulati evolves. Metapulmonary spread of the disease (dissemination) is usually clinically apparent, but can occur silently, although infrequently, to the eyes (Rodenbiker et al. 1981) or kidneys (Petersen et al. 1976). Such dissemination occurs and becomes manifest in the first few weeks to months after onset of primary infection; for example, meningitis became evident about 5 weeks after the initial onset of symptoms (Pappagianis 1988a). Dissemination may not, however, be noted for some years and can occur in the absence of any previously recognized pulmonary focus. In the southwestern USA where coccidioidomycosis is endemic, the overall rate of dissemination in symptomatic cases is 5–7 percent but the rate varies with ethnicity or race. Thus, the primary infection disseminates in one to two per 100 symptomatic adult white males, at a slightly higher rate in Mexicans and Native Americans (Indians) (approximately 5 per 100), but at a markedly higher rate in African-Americans (>20 per 100) and Filipinos (>25 per 100) and other Asians (30 per 100) (Gifford et al. 1936/1937; Smith et al. 1946a, b; Pappagianis 1988b).

Additional risk factors that heighten the risk of dissemination are the following:

- group B blood (Deresinski et al. 1979)
- HLA class II (Louie et al. 1999)

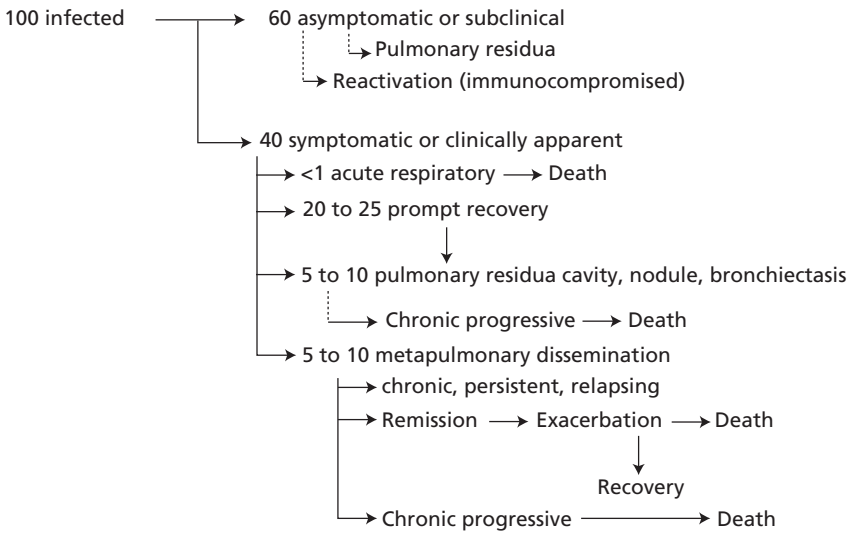

Figure 6 *Forms of coccidioidomycosis in humans. Broken lines indicate infrequently occurring phenomena.*

- pregnancy, particularly when acute primary coccidioidomycosis is acquired during the third trimester (Peterson et al. 1993)
- hematopoietic neoplasms, e.g. lymphoma, AIDS (Deresinski and Stevens 1974; Fish et al. 1990)
- immunosuppression for organ transplant (Cohen et al. 1982; Riley et al. 1994)
- trauma creating a site of lessened resistance (Pappagianis 1985).

Dissemination can affect virtually any tissue and organ, although the gastrointestinal mucosal surface (Weisman et al. 1976) and endocardium have rarely been affected. The skin, bones, and meninges are affected (Huntington 1971). The involvement of various tissues and organs in disseminated disease assures that coccidioidomycosis can be confused with a great variety of infections, neoplasia, connective tissue disorders, etc.; in fact, it has become a 'great imitator' similar to syphilis. A history of travel or residence in 'endemic areas' or (rarely) exposure to products exported from such areas, should prompt consideration of coccidioidomycosis in the differential diagnosis. The coexistence of other diseases (infectious, neoplastic, 'connective tissue,' etc.) must not, however, be overlooked despite confirmation of coccidioidomycosis (Huth 1994).

Immunology

C. immitis can be a primary pathogen producing disease in normal individuals or opportunistic disease in immunocompromised individuals. It is unique among the systemic pathogenic fungi, because its replication in the infected host results in spherules containing tens to hundreds of endospores each of which can, in turn, produce mature endosporulating spherules. Contrast this with the single or few progeny produced by the budding of other systemic pathogens. The mechanism(s) by which *C. immitis* causes disease has not been defined. It may involve toxic action (Gale et al. 1967), enzymatic activity, e.g. proteases (Lupan and Nziramasanga 1986; Resnick et al. 1987; Yuan and Cole 1987; Johnson et al. 2000), and immunological mechanisms: complement-mediated/hypersensitivity/cytokines may contribute to pathogenesis (Magee and Cox 1995).

Mannose is a prominent component of coccidioidal cells (Pappagianis et al. 1961) and may play a role in immune responses via macrophage mannose receptors (Ampel et al. 2004, unpublished).

The immune interactions of host and *C. immitis* have been well reviewed (Cox and Magee 1998). The immunology can be divided roughly into the following categories:

- innate responses of the host
- specific humoral or T-cellular immunity
- induction of protective immunity.

The precise initial events in the interaction between the previously uninfected host and infective arthroconidia have not been well defined. The conidia are of such dimensions that at least some of them may elude the upper respiratory filtration and mucociliary escalator to reach the small bronchi, bronchioles, and alveoli. [Bronchoscopic examination had shown that primary endobronchial disease existed in the apparent absence of pneumonitis (alveolitis) (Birsner 1954).] Although the portal of entry is usually respiratory, infrequently infections have resulted from traumatic introduction of arthroconidia through the skin (Wilson et al. 1953). Experimentally, subcutaneous or intraperitoneal injection of conidia is less likely to result in the severe, progressive, and lethal disease than that induced by respiratory challenge.

In the mouse lung, the arthroconidia elicit a response which includes both macrophages and polymorphonuclear leukocytes (PML). The presence of PML appears to contribute to conversion of arthroconidia to spherules (Baker and Braude 1956). The outer wall of the arthroconidia, before being shed in the evolution to spherules, can, however, have a toxic effect inhibiting phagocytosis and destruction of the arthroconidia by human neutrophil granulocytes (Drutz and Huppert 1983). Mature spherules, by virtue of their size, and packets of newly released endospores embedded in a matrix appear to resist phagocytosis until individual endospores are released from this matrix (Frey and Drutz 1986).

Nevertheless, PMLs may provide an impediment to some morphological forms of *C. immitis* after the activation of complement and production of chemotactic substances in the absence of antibody (Galgiani et al. 1980). This may result after antigen–antibody precipitation as in a fibrin clot (Pappagianis and Zimmer 1990), induction of an 'oxidative burst' with production of antimicrobial H_2O_2 and hypochlorous acid (induced by arthroconidia and by immature but not mature spherules) (Galgiani 1995), production of cationic peptides (Segal et al. 1985), or production of lysozyme which is lethal to *C. immitis* spherules in vitro (Collins and Pappagianis 1973). Some studies suggest that enhanced phagocytosis by PMLs may result after immunization (Wegner et al. 1972).

The induction of a *C. immitis*-specific T-lymphocyte response underlies the major protective response to *C. immitis* (reviewed by Cox and Magee 1998). This has been derived from studies in humans and in experimental animals. A high rate (~100 percent) of humans with primary acute coccidioidomycosis who recovered had positive skin test (delayed-type hypersensitivity) to coccidioidin compared with only about 70 percent of those with unifocal disseminated (extrapulmonary) disease and about 30 percent with multiple sites of dissemination (Smith et al. 1948). Anergy was associated with a poor prognosis in those patients with disseminated disease, and may result from the following:

- excessive fungal antigen or of immune complexes
- induction of suppressor cells
- relative increase of Th2 lymphocytes over Th1 (the latter of greater importance in cell-mediated immunity) (Corry et al. 1996)
- depression of the immune response by fungal cell products.

[However, 15–20 percent of patients with chronic coccidioidal pulmonary cavities are nonreactive to skin tests with coccidioidin, but do not have a poor prognosis or a risk of dissemination from their pulmonary lesion (Smith et al. 1948; Winn 1968).]

It has been proposed that part of the protective immune response to *C. immitis* is related to an opsonizing effect of IgM reacting with surface antigen of *C. immitis* (Pappagianis and Zimmer 1990); but the higher IgG titers are associated with a poorer prognosis (see section on Immunoserology, below) It appears that induction of a *C. immitis*-specific T-lymphocyte reponse underlies the major protective induced immune response to *C. immitis*. In experimental animals, several lines of evidence indicate that immune T lymphocytes and lymphokines are crucial in the protection against *C. immitis* (Beaman et al. 1983). The immune T lymphocytes act not by a direct killing action on *C. immitis* but rather through cytokine activation of monocyte/macrophages (Beaman et al. 1983; Slagle et al. 1989; Ampel et al. 1992; Ampel 2003). Experimentally, interferon-gamma was associated with resistance, interleukins 4 and 10 with susceptibility to *C. immitis* (Magee and Cox 1995; Fierer et al. 1998). Various levels of deficiency of T cell or competency of macrophages may exist in patients who are at higher risk of disseminated coccidioidomycosis. For example, it needs to be determined whether anticoccidioidal enzymatic activities are significantly different in macrophages and this can provide a possible explanation of differences in susceptible versus resistant or immunized hosts.

Resistance (immunity) to second exogenous infection follows subclinical infections (detected by positive skin test) and complete recovery from clinically apparent infection only. Only four cases of second exogenous (re)infection have been documented in >30 000 cases of coccidioidomycosis. Only one was a naturally acquired infection but in an immunocompromised individual. Three others were laboratory acquired (Pappagianis 1999). Endogenous reactivation of a previously arrested, non-disseminated, coccidioidal infection can occur as a result of immunosuppression: iatrogenic as with organ transplantation, from infection with HIV, or through development of a hematopoietic–lymphoreticular malignancy. Reactivation of a previously disseminated coccidioidal infection, even after apparently successful antifungal therapy, is not uncommon (Stevens 1995).

It had been demonstrated by Rixford (Rixford and Gilchrist 1896) that prior infection with *C. immitis* rendered a dog resistant to (parenteral) reinfection. The resistance conferred upon humans by prior infection led to experimental immunization in laboratory animals. In 1951 it was demonstrated by C. E. Smith that injection of the hyphal/arthroconidial form of living avirulent *C. immitis* in mice induced resistance to intraperitoneal challenge. Injection of virulent *C. immitis* in mice or monkeys provided protection against lethal respiratory challenge (Pappagianis et al. 1960). Killed *C. immitis* also afforded protection (Friedman and Smith 1956; Levine et al. 1960). Of the various morphological forms used in nonviable vaccines, the mature spherule (particularly its cell wall) proved to be the most efficacious (Levine et al. 1961). These immunizations did not prevent infection following respiratory challenge but did prevent progressive, lethal disease. After tests for safety of the killed spherule vaccine, tests for protective efficacy in humans showed that the killed spherule vaccine did not prevent clinically apparent coccidioidomycosis (Pappagianis and the Valley Fever Vaccine Study Group 1993). The inadequate response of humans may have resulted from the relatively small dose of antigen that had to be used because of the inflammatory effect of whole spherules injected intramuscularly. It is possible that isolation and/or synthesis of the immunogenic component away from irritating cell wall components, e.g. chitin, may provide a tolerable and effective vaccine for humans.

Some candidate subcellular vaccines that have exhibited protection against respiratory challenge in mice include derivatives of mechanically disrupted spherules (Zimmermann et al. 1998), a soluble proline-rich antigen (PRA) developed by Galgiani and colleagues (Shubitz et al. 2002), which proved to be the same as antigen 2 (Ag2) developed by Cox and colleagues (Zhu et al. 1996); and antigens including coccidioides-specific antigen (CSA) of Cole et al. (2004). Recombinant peptide forms of Ag2/PRA and CSA, when mixed or chemically combined, have the appropriate properties and immunogenicity that may permit them to be tested in nonhuman primates and humans.

Screening immunization of a cDNA library has led to another antigen with protective activity in mice (Ivey et al. 2003).

Histopathological response

Coccidioidal lesions can generally be termed pyogranulomatous, but in fact a variety of histopathological responses can be detected: tuberculosis-like granulomata, caseation necrosis with or without (more often) calcification, hyalinization-fibrosis, fibrinous pleuritis. Endospores attract PML whereas the mature spherules evoke a mononuclear/macrophage response (Figure 1). Thus, abscesses and tubercles may be side by side (Huntington 1971). *Coccidioides* in the skin evokes a proliferative ('pseudoepitheliomatous') response in the epidermis. The synovial membranes produce a villous

response in coccidioidal arthritis. Bones have lytic lesions (occasionally proliferative) in the human, lytic or proliferative in dogs. In old pulmonary lesions (coccidioidomas), immature (non-endosporulating) spherules are often embedded in fibrocaseous material. In the absence of identifiable *C. immitis*, the granulomatous reaction may resemble that of other diseases such as sarcoidosis. Peripheral (bloodstream) eosenophilia can occur and on occasion the acute coccidioidal pulmonary disease can resemble 'eosenophilic pneumonia' of other etiologies (and disastrous therapy with adrenocorticosteroids may be applied).

In coccidioidal meningitis, the cerebrospinal fluid (CSF) exhibits a pleocytosis which, early on, may have a preponderance of PML and eosenophilia, but usually the lymphocytes predominate. Cerebral arteritis can accompany coccidioidal meningitis.

Treatment

Most patients with coccidioidomycosis could be managed successfully without specific antifungal therapy but, if necessary, the disease can be treated medically or surgically. The decision to treat or not to treat, and the mode of therapy depend on the clinical stage, on risk factors in the hosts, and the type and location of lesions. The variability in the clinical course of the disease, whether treated or untreated, has made evaluation of therapy difficult. More than one therapeutic modality may have to be applied.

MEDICAL THERAPY

Currently available therapy includes preparations of the polyene amphotericin B (AMB), including lipid or liposomal forms, and azoles. The azoles are fungistatic. The AMB under some circumstances can be fungicidal but with clinical concentrations is usually fungistatic. There is a lack of well controlled therapeutic studies which has led to uneven and sometimes uncertain application of therapy. Between the introduction of AMB in the treatment of coccidioidomycosis in humans in 1956 (Fiese 1957), and the introduction of the azoles 25 years later, the usually benign course of primary coccidioidomycosis prompted a conservative approach – to avoid the undesirable side effects of parenteral AMB, particularly nephrotoxicity and adverse effects on the hematopoietic system. Miconazole, also given parenterally, had a short-lived application in disseminated coccidioidomycosis. After the introduction of the azoles that could be taken by mouth [ketoconazole (KTZ), fluconazole (FLU), and itraconazole (ITR)] and were relatively free of undesirable side effects, these oral medications were used initially to treat disseminated disease (Tucker et al. 1990a, b; Diaz et al. 1991; Galgiani 1993; Galgiani et al. 1988, 2000). In some locations, the routine early use of the relatively benign triazoles has become customary in the treatment of suspected or confirmed cases of coccidioidomycosis without controlled evaluation of the efficacy at this stage of the disease, i.e. it is not known whether such treatment hastens recovery or prevents complications such as extrapulmonary spread of the disease or development of pulmonary residual lesions. Despite uncertainty regarding the usefulness of treatment in acute primary coccidioidomycosis, the presence of certain threatening conditions (severe intrapulmonary disease, risk factors for dissemination) and unfavorable laboratory values (such as peripheral blood eosinophilia and climbing complement fixation (CF) titer) gives the justification for treatment.

KTZ is now infrequently used in human coccidioidomycosis in the USA. Variconazole, a triazole as are FLU and ITR, has had limited use in coccidioidomycosis but has appeared effective even against meningitis following failure of FLU therapy (Cortez et al. 2003).

Treatment is almost always indicated for patients with demonstrated or surmised disseminated disease, or with rapidly progressive primary pulmonary disease. AMB is indicated for the latter, for widespread extrapulmonary lesions, infected pregnant women (the AMB appears to have little adverse effect on the fetus), and osseous lesions. [The place of the azoles in the treatment of humans with osseous lesions is not well defined (ITR may be preferred), but in the dog KTZ appears to lead to an improvement in osteoarticular disease (Wolf and Pappagianis 1981).] For more indolent disseminated disease, the azoles can be used, and which to use may be guided by the side effects (greater with KTX) or expense (greater with FLU than with KTZ or ITR). However, other properties may also influence the selection: excellent penetration of FLU into the CSF (appropriate for treatment of meningitis); short half-life of KTZ compared with those for FLU and ITR (Tucker et al. 1990a). Significant interaction with other drugs requires close attention when the azoles are used (e.g. with rifampin, cyclosporin, warfarin, and terfenadine). Acquisition of resistance to FLU by *C. immitis* has been suggested but not proven.

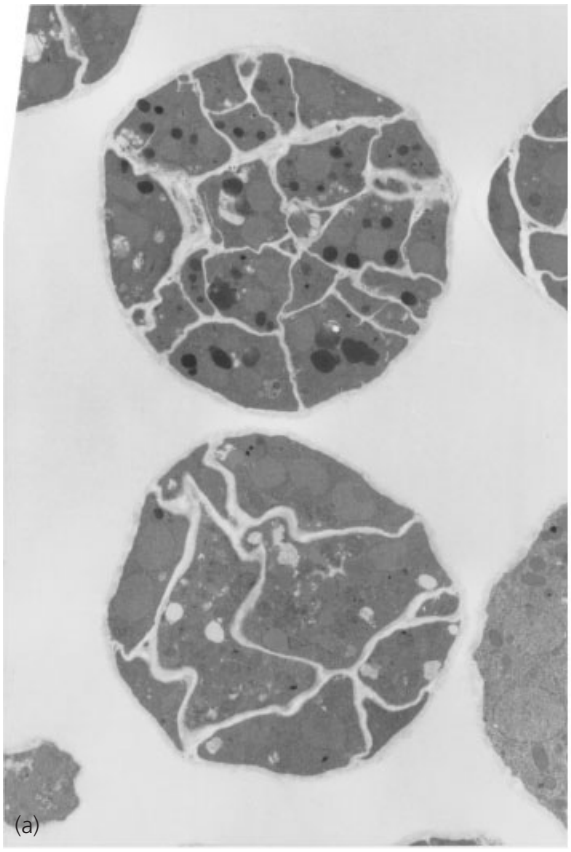
Two major problems accompany medical therapy: the long-term therapy of coccidioidomycosis (usually months or years) is very expensive, and there is uncertainty as to when to stop treatment. Relapses have followed seemingly successful treatment, especially with the azoles (Dewsnup et al. 1996).

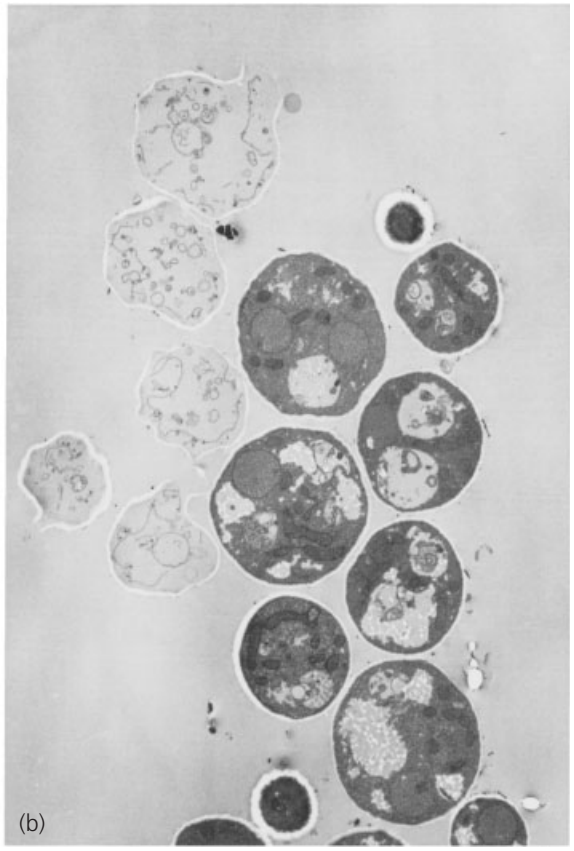
FUNGICIDAL AGENTS

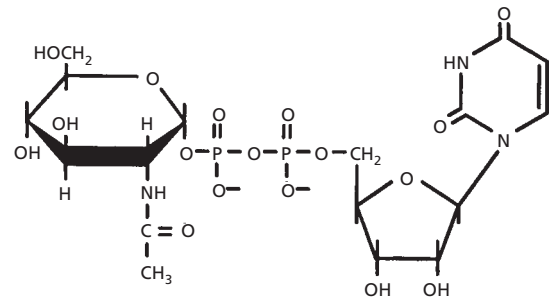
These are needed, because currently used chemotherapeutic agents have not killed cells in the host. Experimentally, nikkomycin Z, an inhibitor of synthesis of cell wall polysaccharide by chitin synthase, has proved to be curative (Hector et al. 1990) (Figure 7).

SURGICAL THERAPY

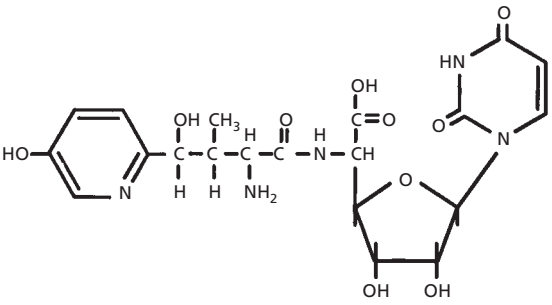
Surgical approaches are indicated as diagnostic and therapeutic procedures for numerous coccidioidal lesions.







UDP-*N*-acetylglucosamine



(c) Nikkomycin Z

Figure 7 (a) *Transmission electron micrograph of 33-hour-old spherules produced in vitro, untreated* **(a)** *and those exposed to nikkomycin Z 2 μg/mL for 24 hours* **(b)**. *Untreated spherules exhibit an intact cell wall and segmentation towards formation of endospores. In the presence of nikkomycin there is a decrease in the size of the spherules, little or no cell wall was formed and the ghosts of some spherules are collapsing. (From Pappagianis (1989) with permission.)* **(c)** *Comparative structure of antifungal nikkomycin Z and UDP-N-acetylglucosamine.*

Biopsy (this may be excisional) of a solitary pulmonary nodule is in the diagnostic category; this type of nodule must be distinguished from neoplastic or other infectious nodules which have not yielded a diagnosis with non-invasive procedures (Forseth et al. 1986). Coccidioidal pulmonary cavities, and their associated complications such as hemorrhage, rupture into the pleural space, or formation of a bronchopleural fistula, may require surgical correction (Cunningham and Einstein 1982).

Drainage of abscesses and empyema, removal of infected bone or joint tissue, and immobilization of a joint by arthrodesis are additional therapeutic surgical procedures (Bried and Galgiani 1986). Stabilization of vertebrae infected with *C. immitis* has been accomplished (Herron et al. 1997).

Surgical placement of prostheses, such as insertion of an Ommaya reservoir and catheter into the lateral ventricle or cisterna magna, may help in the treatment of coccidioidal meningitis (Zealear and Winn 1967).

Surgical procedures are usually carried out with concomitant antifungal medical therapy.

LABORATORY DIAGNOSIS

Direct examination

Microscopic demonstration of *C. immitis*, particularly the endosporulating spherules, provides the most direct and secure method of diagnosis. Detection may be attempted with bronchial washings, exudates, and sputum (the last is often unreliable because of confusing artifacts). Synovia or other body fluids, e.g. pleural, pericardial, or peritoneal, may reveal presence of the organism though the corresponding tissue is more likely to yield *C. immitis* microscopically (or by culture). The endosporulating spherules or other forms can be identified in preparations treated with potassium hydroxide or stained with hematoxylin and eosin (H&E) or Papanicolaou stain, but they may be more readily distinguished when stained by methenamine silver or periodic acid–Schiff (PAS), particularly when the latter is used without a counterstain (Huntington 1971). *C. immitis* can be visualized in gram-stained sputum or body fluids, but this has not been a widely advocated method. Various sized forms of *C. immitis* may be seen, and in some lesions, particularly chronic ones, small immature spherules without endospores may be observed and can resemble *Blastomyces dermatitidis* (Figure 3). The presence of chitin in the cell wall permits fluorescent staining of *C. immitis* in sputum or other body fluids using Calcofluor white M2R (Polysciences Inc.) or its equivalent Fluorescent Brightener 28 (Sigma Chemical Co.). Fluorescent antibody staining (of limited availability) has shown a desirable specificity and can be used when the usual histopathological examination has not yielded a definitive answer.

In some tissues, e.g. pulmonary cavities, the hyphal form may be observed but is not definitive for *C. immitis* and further confirmatory studies are required, e.g. conversion of hyphal to endosporulating spherule by inoculation of laboratory animals or special culture media. A wide range of tissue reactions is evoked by *C. immitis* – suppurative, granuloma, pyogranuloma, caseation necrosis with or without calcification, hyaline or fibrotic changes. Thus, even if the characteristic endosporulating spherules are not seen, the diagnosis of coccidioidomycosis should not be rejected based on the nature of the host response.

Culture

C. immitis is hardy and non-exacting in its nutritional requirements, being able to grow in simple media containing salts and ammonium acetate or ammonium lactate as its sources of energy, carbon, and nitrogen. It can grow in media with an acidic pH <3.0 and alkaline pH >9.0). (The tolerance of a high pH may underlie its ability to survive in the alkaline soils of the endemic areas, and in the selective action of NH_4OH added to yeast extract/phosphate medium.) It can grow at 22°C and at 40°C, but its optimum for hyphal growth is about 30°C. In vitro, the conversion from hyphal to spherule/endospore form is enhanced by incubation at 40°C but it can be maintained in the spherule/endospore phase at 37°C. Exposure to 46°C for 2 hours is tolerated but it is killed in 4 minutes at 60°C. Inoculation of sputum, exudates, tissues, onto many of the commonly used culture media will yield satisfactory growth, including: sheep blood agar, brain heart infusion, beef infusion glucose, Sabouraud's glucose agar, glucose/yeast extract agar. The glucose (2 percent)/yeast extract (1 percent) agar (2 percent) provides excellent yields of arthroconidia whereas the peptone-containing Sabouraud's glucose agar can diminish the yield of arthroconidia.

Culture of the blood may yield the organism, but patients with coccidioidal fungemia are frequently very ill and in the preterminal stage of their coccidioidomycosis. Care must be taken to permit recovery of *C. immitis* in specimens that may contain other organisms. Treatment of sputum with alkali or hypochlorite for recovery of *Mycobacterium tuberculosis* can inactivate *C. immitis*. Recovery of *C. immitis* may, however, be enhanced by mucolytic agents such as *N*-acetyl-1-cysteine and dithiothreitol. Competing organisms can be minimized by the addition of the antifungal cycloheximide and antibacterial chloramphenicol. Before diagnostic animal inoculation, specimens can be treated with penicillin G and streptomycin (or comparable aminoglycoside) to reduce possible infection with bacteria. Isolation from the soil can entail similar plating or inoculation of laboratory animals – mice being the most convenient.

Faint grayish-white growth becomes visible in 48 hours on several media; it becomes clearly evident as a

cottony to weblike growth in 48–72 hours. Although rarely necessary, it is advisable to retain cultures for 2–3 weeks before discarding them as negative.

Typical gross morphology is exhibited by most isolates of *C. immitis* but atypical colonial growth does occur. For this reason and because the hyphal/arthroconidial form of *C. immitis* resembles other nonpathogenic fungi, it is essential to carry out definitive identification. This can be achieved by demonstrating the spherule/endospore phase after inoculation into laboratory animals or into special culture media.

More recently, a DNA hybrid protection assay (Gen-Probe, Inc.) has proved to be a sensitive and rapid way to identify isolates as *Coccidioides* (Beard et al. 1993). Ribosomal RNA (rRNA) is extracted from the suspect organism and allowed to react with specific DNA from *C. immitis* to which is attached a potentially luminescent acridinium ester. If the rRNA is of coccidioidal origin, it will react with its complementary DNA, and this protects the ester linkage against hydrolysis, thus yielding luminescence. Heterologous rRNA will not interact with the coccidioidal DNA, and the acridinium ester will be hydrolyzed and thus not yield luminescence. The method appears to be quite specific and requires very little of the mycelial growth form.

Another in vitro test which has served for several years as a specific test for *C. immitis* is the exoantigen test (Standard and Kaufman 1977). The suspect culture is grown for several days on a slant culture. An aqueous solution of thimerosal is added to the slant to sterilize the culture and to extract antigen. The antigen-containing supernatant is then tested by immunodiffusion using specific anticoccidioidal antibody to demonstrate the presence of antigen specific for authentic *C. immitis*. A 19 kDa polypeptide with serine protease activity may represent the '*Coccidioides immitis*-specific' antigen (Pan and Cole 1995).

The indispensable condition for morphological identification is demonstration of endosporulating spherules. This can be achieved by intraperitoneal or intranasal inoculation of mice or intratesticular inoculation of guinea pigs. If the animals become overtly ill, tissue with visible lesions can be examined microscopically in a squash preparation or permanent histological sections. If no illness develops, mice should be sacrificed at 7–10 days. If no lesions are evident, subcultures should be made from the tissues, and additional mice sacrificed at 14 and 21 days. Intraperitoneal inoculation usually suffices but some isolates of lesser virulence may only be recoverable after intranasal inoculation.

Immunoserology

Immunological tests have been very useful in epidemiologic studies and in the diagnosis and management of cases of coccidioidomycosis [reviewed by Pappagianis 2001 (in Ampel 2001) and Pappagianis and Zimmer 1990]. They represent sensitive and specific tests which can assist in the diagnosis when there is not ready access to sputum or tissue, and to obviate invasive procedures. In the early application and evaluation of these procedures, conversion to skin test positivity appeared to precede the detection of antibody (Smith et al. 1956). However, more recent studies have indicated that antibody can be detected before the skin test becomes positive. Therefore, a negative skin test should not preclude a diagnosis of coccidioidomycosis nor the use of serological tests (Table 2).

Skin testing can be carried out with lysate-culture filtrate of the hyphal phase (coccidioidin) or lysate of the spherule/endospore phase (spherulin) (Levine et al. 1973). Although some individuals yield immediate-type reactions, the delayed cutaneous hypersensitivity reaction (readings at 24–48 hours, therefore earlier than tuberculin reactivity) represents the evidence of past or current infection. Only recent conversion to positivity is of assistance in the diagnosis of an acute primary coccidioidal infection. A reaction in a healthy individual denotes resistance to exogenous reinfection. Cross-reactivity in individuals previously infected with *H. capsulatum* can be observed, but does not represent a serious problem.

Failure to react to the skin test (anergy) may develop in about half the patients with disseminated coccidioidomycosis. However, 15–20 percent of patients with non-disseminated disease, e.g. a single chronic pulmonary cavity or nodule, fail to react (Winn 1968).

In vitro lymphocyte stimulation by coccidioidal antigen is a correlate of skin test responsiveness but has not supplanted the simple intracutaneous test.

In primary non-disseminating coccidioidomycosis, a regular sequential response is noted, indicated by production of two kinds of antibody: a precipitin and a complement-fixing antibody (Figure 8). The former was originally detected by a tube precipitin (TP) test (soluble, heat-stable antigen present in coccidioidin yielded a precipitate when mixed with serum of a patient with early, acute coccidioidomycosis) (Smith et al. 1956). It was later shown that the reaction could

Table 2 *Application of serologic tests in coccidioidomycosis*

	Detection of	
	IgM	IgG
Tube precipitin (TP)	Yes	No
Latex particle agglutination (LPA)	Yes	No[b]
Immunodiffusion = TP (IDTP)	Yes	No
Complement fixation (CF)	No (rare[a])	Yes
Immunodiffusion = CF (IDCF)	No	Yes
Counterimmunoelectrophoresis (CIE)	Yes	Yes
Enzyme-linked immunoassay (EIA)	Yes	Yes

a) Rarely positive CF in presence of positive IDTP (IgM, and absence of detectable IgG by IDCF).
b) Occasional positive LPA in presence of detectable IgG but not IgM by immunodiffusion.

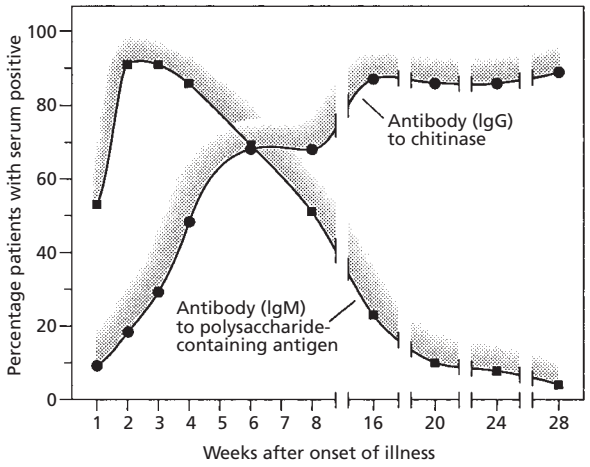


Figure 8 *Sequential antibody response in humans infected with* Coccidioides immitis. *The shaded zones represent the greater sensitivity, though not precisely defined, of more recent immunodiffusion and enzyme immunoassay tests for the detection of the IgM or IgG than the results (solid squares and circles) obtained using a TP and CF test by Smith et al. (1956).*

also be detected by agar gel double immunodiffusion (ID). The reaction is referred to as immunodiffusion corresponding to the tube precipitin (IDTP) test; and the responsible antibody was found to be IgM. This antibody could also be detected by antigen-coated latex particles and by enzyme-linked immunoassay (EIA). The antigen that reacts with the IgM appears to be mainly polysaccharide but has also been described in connection with a 120 kDa glucosidase (Kruse and Cole 1992), or a 21 kDa proteinase (Resnick et al. 1987) that can be released into the culture medium (Zimmer and Pappagianis 1989). This IgM antibody is detectable in more than 50 percent of patients with acute coccidioidomycosis by a week after the onset of symptoms. It is subsequently detectable (between 2 and 3 weeks of illness) in more than 90 percent of patients, and gradually fades although, with currently available methods, more than 10 percent of patients still have detectable antibody 6 months after onset of illness. There is no clear correlation between its titer and prognosis. It has been detected in the blood of newborns whose mothers had coccidioidomycosis and the anti-coccidioidal IgM, but this did not denote presence of the disease in the neonate. Presence of the IgM in the CSF has been infrequent but only associated with coccidioidal meningitis.

The antibody appearing later was originally detected by CF (Smith et al. 1956) and its titer clearly correlated with the extent and severity of the disease. It did not yield a precipitate with its corresponding antigen in a liquid milieu, but in a gel (agar, agarose, Gellan, Kelco of Merck & Co., Inc.) the antibody with its corresponding antigen produced a precipitate referred to as immunodiffusion corresponding to complement fixation (IDCF) (Figure 9). The antibody can also be detected by EIA (Pappagianis and Zimmer 1990; Gade et al. 1992). The responsible antigen, a protein of approximately 110 kDa, or 48 kDa under reducing conditions (Zimmer and Pappagianis 1988), is a chitinase (Johnson and Pappagianis 1992), which is released by the maturing then rupturing spherule. [The coccidioidal DNA which encodes for this chitinase has been cloned in *Escherichia coli* which has produced enzymatically and serologically active chitinase (Zimmermann et al. 1996).] The corresponding antibody appears to be primarily IgG. Its titer generally rises with worsening of the disease, and decreases with improvement of the patient. A titer above 1:16 is often associated with metapulmonary dissemination, e.g. to the skin, a bone or even the meninges (Smith et al. 1956). With this last, there can be lethal disease even though the CF titer in the serum is less than 1:16. In most patients with meningitis, antibody can also be detected in the CSF but the serum must always be tested along with the CSF

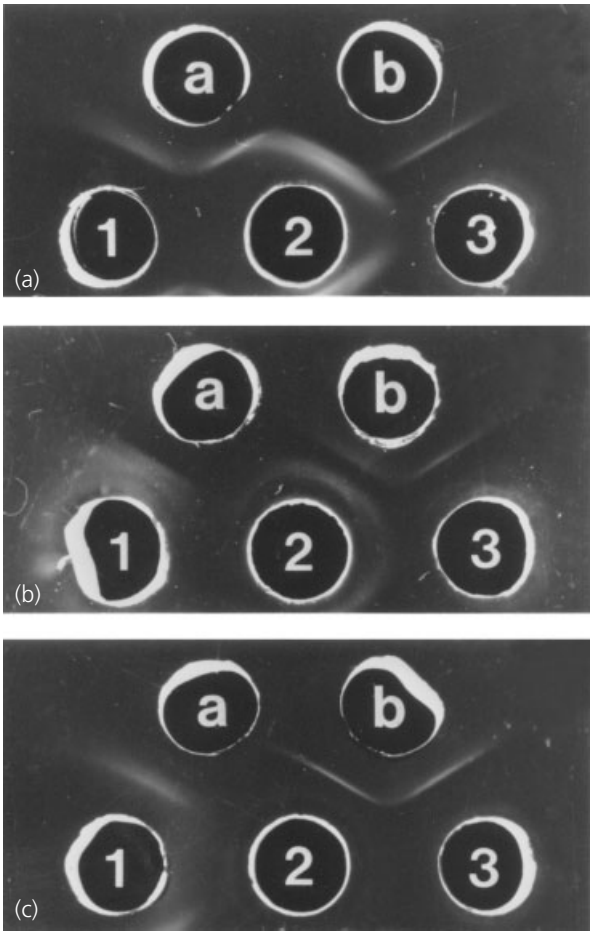

Figure 9 *Agar gel immunodiffusion indicating the detection of the usual antibodies (IgM and IgG) in human serum at different stages after infection. Well 2, patient's serum; wells 1 and 3, control IgM- and IgG-positive sera, respectively. Wells a and b contained coccidioidal antigen.* **(a)** *Early infection, IgM present;* **(b)** *later stage, both IgM and IgG present;* **(c)** *even later, only IgG detectable.*

because the CSF of some patients may be seronegative early in the course of meningitis. Testing synovial and other cavity fluids may be helpful in following the disease in corresponding anatomic sites.

Although the serological reactivity may obviate the need for invasive procedures, mediastinoscopy, or bronchoscopy, when possible, and recovery of the organism must be attempted. It is important to remember that in suspected early coccidioidomycosis, the tests for IgM are needed because the coccidioidal IgG may not be detected at that stage.

In the usual patient, serological reactivity is of considerable assistance for diagnosis and prognosis. However, some patients with immunosuppressive conditions (iatrogenic as for organ transplantation, or AIDS) may fail to produce a detectable antibody response (Fish et al. 1990). However, appropriate testing (concentrating serum prior to testing) has reduced seronegativity in AIDS patients with coccidioidomycosis to less than 10 percent.

It has been shown that detection of antigen may be accomplished before the detection of the antibodies described above, and this may provide an additional early serodiagnostic test and one useful in immunocompromised patients (Galgiani 1992).

Histopathology

Gross lesions may provide a clue to the histopathological changes which may involve a pyogranulomatous response with granulocytes, including both neutrophils and eosinophils, macrophages, multinucleate giant cells with palisading epithelioid cells, caseation necrosis, and hyalinization or fibrosis with lymphocytes at the periphery. The granulomatous changes, fibrosis and, occasionally, calcification, may represent chronic lesions, but only the presence of *C. immitis* distinguishes these from lesions of many other diseases. Vasculitis with perivascular inflammation and endarteritis obliterans has been described in association with coccidioidal meningitis/encephalitis.

The suppurative reaction may be extensive, but microabscesses only a few hundred micrometers in diameter may be found adjacent to granulomas. The former probably represent a response to released endospores, the latter a response to the larger spherules. Occasionally, the surface of mature spherules stained with H&E demonstrates a rough eosinophilic deposit similar to the Splendore–Hoeppli phenomenon associated with other fungi.

In addition to H&E and Papanicolaou's stains, the polysaccharide stains PAS and methenamine silver are useful for detection of *C. immitis*. Methenamine silver may stain the *C. immitis* diffusely dark, so that the internal structure, e.g. endospores in a spherule may not be clearly visible. PAS can provide better definition of the spherule/endospore phase. The so-called 'Schiff-positive dust' (Huntington 1957) stained by PAS can occasionally be seen in the cytoplasm of multinucleate giant cells and may represent remains of cell wall polysaccharide, digested autolytically by *C. immitis*, or by host cell enzymes, e.g. lysozyme (Collins and Pappagianis 1973), or chitinase. Calcofluor, which produces fluorescence with chitin in the cell wall, can be used to detect *C. immitis* in bronchoalveolar lavage specimens.

Histoplasmosis

RAM P. TEWARI, L. JOSEPH WHEAT, AND L. AJELLO

Etiologic agents: historical background and natural history 1
Host response 4
Laboratory diagnosis 13
References 19

Histoplasma capsulatum, like Caesar's Gaul, is tripartite. Taxonomically, it has been subdivided into three varieties, each with its own distinctive and defining characteristics. The varieties are validly referred to as *H. capsulatum* var. *capsulatum*, *H. capsulatum* var. *duboisii*, and *H. capsulatum* var. *farciminosum*. As might be expected, each of them causes a distinct type of histoplasmosis, designated respectively as histoplasmosis capsulati, histoplasmosis duboisii, and histoplasmosis farciminosi. They also have a varied geographical distribution. Rather than divide the genus *Histoplasma* into varieties and classes, Kasuga and colleagues propose seven phylogenetic species based on genetic isolation (Kasuga et al. 2003). The *capsulatum* variety is cosmopolitan, being endemic in all the world's continents. The *duboisii* variety has the most limited areas of endemicity, being restricted essentially to the central part of the African continent between the tropics of Cancer and Capricorn, and to the offshore island of Madagascar in the Indian Ocean. *H. capsulatum* var. *farciminosum* is not known to occur or to have been introduced anywhere in the New World. Its endemic areas are currently located in Africa, eastern Europe, the Middle East, Asia (including Japan and the Philippines), and the Far East. All three varieties occur as saprophytic, mitosporic molds (Fungi imperfecti) in their ecological niches in nature or in the laboratory cultures at room temperature (about 25°C). In the tissue of their mammalian hosts, however, or when incubated at 37°C on rich media, they transform into unicellular yeast-like budding organisms.

ETIOLOGIC AGENTS: HISTORICAL BACKGROUND AND NATURAL HISTORY

Histoplasma capsulatum var. *capsulatum* – Darling 1906

The genus *Histoplasma* was established in 1906 when Darling (1906) described the first case of histoplasmosis capsulati in Panama and named its etiologic agent *H. capsulatum*. He was under the impression that this organism was a protozoan closely related to the species of *Leishmania*, but 'the differences are so marked and the lesions so unusual that I feel the case is a unique one.' The mycotic nature of this 'protozoan' was inferred by da Rocha-Lima of Brazil, who, while in Germany, compared histological sections from Darling's Panamanian human case with sections from east African cases of equine epizootic lymphangitis (histoplasmosis farciminosi) as well as visceral leishmaniasis (kala-azar). The equine cases (*Equus asinus* × *caballus* and *E. caballus*) were known to be caused by the fungus *Cryptoccocus farciminosus*, now designated *H. capsulatum* var. *farciminosum*. As a result of these comparative histological studies, da Rocha-Lima concluded that Darling's *H. capsulatum* was a fungus and not a protozoan, based on the intracellular occurrence of the unicellular tissue forms of the organisms and similarities in their morphology and tinctorial reactions (da Rocha-Lima 1912, 1912–13).

It remained for De Monbreun (1934) of Vanderbilt University in Nashville, TN to isolate the *capsulatum*

variety of *H. capsulatum* for the first time. He clearly described and depicted the in vitro mycelial and unicellular forms of this mold and proved that it was dimorphic. He also reproduced the critical clinical and histopathological features of Darling's histoplasmosis capsulati in two monkeys (*Macacus rhesus*) after intravenous injection of the yeast form of his historic isolate.

Development of the histoplasmin skin test also was an important milestone in our understanding of histoplasmosis (Palmer 1945). These studies provided the initial evidence that histoplasmosis often caused a benign and usually asymptomatic infection characterized by pulmonary calcification. Subsequently this approach established our understanding of the geographical distribution of histoplasmosis in the USA (Edwards et al. 1969).

The astuteness of De Monbreun as an investigator was revealed when he stated that 'the saprophytic form of *Histoplasma capsulatum* probably exists free in nature.' This probability turned into reality in 1949 when Emmons of the National Institutes of Health in Bethesda, MA reported the isolation from two soil samples collected under the edge of an outbuilding on a Virginia farm where histoplasmosis capsulati had been proven in 7 of 43 trapped brown rats (*Rattus norvegicus*) (Emmons et al. 1947).

The geophilism of *H. capsulatum* var. *capsulatum* and its growth as a saprophyte in soil were irrefutably established by Emmons when he detected and photographed the diagnostically important tuberculate macroconidia of that fungus in the supernatant of suspensions of soil specimens that had been proven to be positive for that mold by passage through laboratory mice (Emmons 1949).

The saprophytic existence of *H. capsulatum* in avian and chiropteran habitats was established respectively by field studies (Zeidberg et al. 1952; Emmons 1959). Although birds are not known to be infected by the *capsulatum* variety (Mengis and Habermann 1955), transitory infections in chickens (*Gallus gallus*) and pigeons (*Columba livia*) were, however, reported by Schwarz et al. (1957) when their birds were inoculated intravenously with 500 000 yeast-form cells/ml of the *capsulatum* variety – a highly improbable type of challenge to occur in nature. The innate resistance of birds, perhaps, may be attributed to their normally high body temperatures of 42–43°C.

Bats of a wide variety of genera (24) and species (33) have been found to be infected by *H. capsulatum* var. *capsulatum* (Schacklette et al. 1962; Ajello et al. 1995, 1996) and one species (*Nyceteris hispida*) by the *duboisii* variety in Nigeria (Gugnani et al. 1994).

Among humans, isolated cases and outbreaks of histoplasmosis capsulati almost invariably can be traced to sites associated with accumulations of bird and bat guanos in many parts of the world (Ajello 1964; Sacks et al. 1986). The *capsulatum* variety of *H. capsulatum* thrives in such soils, especially in caves, chicken coops with dirt floors, attics, and the hollow walls of homes, industrial plants, schools, church steeples, etc., and the roosts of gregarious birds, such as blackbirds, oil birds, pigeons, seagulls, and starlings (Ajello 1964; Smith and Furcolow 1964; Dean et al. 1978).

Disturbances of such sites create aerosols laden with infectious propagules of *H. capsulatum* var. *capsulatum*. When inhaled, these aerosols result in infections varying in degrees of severity depending on the site of the inoculum and the immunological status of the individuals involved.

A possible explanation for the predilection of the *capsulatum* variety for avian bat habitats was suggested by Vining and Weeks (1974). These investigators found significant chemical differences between soils positive and negative for this fungus. The positive soils were richer in nitrogen and phosphorus as well as organic matter and water-holding capacity. Previously, Smith and Furcolow (1964) had found that growth-stimulating substances were present in infusions of starling feces.

Knowing the relationship between avian and chiropteran habitats and the *capsulatum* variety of *H. capsulatum*, decontamination procedures for clearing sites found to be infested by that fungus have been developed (Smith et al. 1964; Tosh et al. 1967). Formalin at a concentration of 3 percent was found to be the most effective agent. Application procedures and costs for decontaminating a 3.23 hectare (7 acre) bird roost site were presented by Bartlett et al. (1982). The total cost of this project was $US75 000.

For a long time *H. capsulatum* was considered to be an asexual mold classified in the Fungi imperfecti or Deuteromycetes grouping where all fungi without known sexual states were classified under a system based on spore groups developed by Saccardo (1899). However, in 1972, Kwon-Chung discovered that the variety *capsulatum* of *H. capsulatum* was heterothallic and described its perfect state. It proved to be an ascomycete and was named *Emmonsiella capsulata* (Kwon-Chung 1972). Isolates of the *capsulatum* variety were found to be one or the other of two mating types designated as (a) and (b) or (+) or (−). When the opposite mating types are paired on appropriate media, cleistothecia are formed that are loosely composed of a core group of ascogenous hyphae surrounded by tightly coiled hyphae. When mature, the cleistothecia contain club-shaped asci (3–5×10–16 μm), each of which contains eight globose ascospores measuring 1.5 μm in diameter. Four of the eight ascospores will turn out to be of the (+) mating type and four of the (−) mating type (Kwon-Chung and Bennett 1992, pp. 497–8).

Kwon-Chung (1975) investigated the genetic relationship of the *capsulatum* variety to the *duboisii* variety. It was thus determined that isolates of the *duboisii* variety successfully mated with the appropriate opposite mating types of the *capsulatum* variety giving rise to a teleomorph identical to *E. capsulata*.

The ascospores from the cleistothecia of the *duboisii* matings did not germinate. When injected into mice, however, the ascospores proved to be pathogenic, converting into yeast-form budding cells. The tissues from the experimentally infected mice, when cultured, gave rise to colonies typical of *Histoplasma* (Kwon-Chung and Hill 1981). In 1986, Vincent et al. demonstrated that the restriction enzyme digest pattern of mitochondrial DNA from the *capsulatum* and *duboisii* varieties supported their varietal status.

In 1979, McGinnis and Katz compared herbarium specimens of *Ajellomyces dermatitidis* and *E. capsulata* and concluded that the differences between these two genera were too insignificant to warrant maintenance of the genera as separate entities. As a result, *E. capsulata* was reduced to the status of a synonym of *A. capsulatus*. The species of *Ajellomyces* are classified in the order Onygenales, family *Onygenaceae* of the phylum Ascomycota (Sigler 1993).

Histoplasma capsulatum var. *duboisii* – Vanbreuseghem (1952) – Ciferri 1960

Although much is known about the natural history of the *capsulatum* variety, relatively little is known about the *duboisii* variety in respect to its niche in nature. This variety was first isolated in culture and identified as the cause of a new form of histoplasmosis by Duncan in 1943. He did not, however, publish his findings until 1947 and 1958 (Duncan 1947, 1958). In the meantime, Vanbreuseghem, in a case report by Dubois et al. (1952), described the agent as a new species of *Histoplasma* and named it *Histoplasma duboisii*. Duncan, in his 1958 paper, fully described the clinical, histological, and mycological features of the disease that had been contracted by an English mining engineer who had worked for 6 years in the Gold Coast Colony now known as Ghana. Duncan found that the mycelial form of his African isolate was indistinguishable from that of *H. capsulatum*. It was recognizable as being different by the large size of the tissue forms of the pathogen, which measured 8–12 μm and up to 15 μm in the longer axis. These dimensions were in striking contrast to the in vivo measurements of the tissue-form cells of the *capsulatum* variety, which predominantly range in size from 3 to 4 μm in diameter. It is as well to recall, however, that some isolates of the *capsulatum* variety also produce large yeast-like cells of 6–17 μm in diameter in vitro and in vivo, as emphasized by Drouhet and Schwarz (1956). As a matter of fact, these two investigators stated that 'the great variability found in the strains studies does not seem to indicate justification of assembling the African strains with large cells in a distinct species.' Such an opinion was shared by Ciferri in 1960, who named it *H. capsulatum* var. *duboisii*.

Four years later, the disease term 'histoplasmosis duboisii' was coined by Cockshott and Lucas (1964). They succinctly stated that the 'American isolates and African isolates have negligible differences between their mycelial phases but distinct morphological differences in their parasitic stages whether naturally acquired or experimentally induced infections.' In 1975, Kwon-Chung solidly established the validity of the status of *H. duboisii* as a variety of *H. capsulatum* by successfully mating the tester strains of *A. capsulatus* (as *E. capsulata*), the teleomorphic state of the *capsulatum* variety, with varieties of the *duboisii* variety.

In the disseminated cases of histoplasmosis duboisii, a characteristic clinical picture is presented, revealing bone and subcutaneous abscesses and pleomorphic skin lesions. A definitive diagnosis rests on the demonstration of large, ovoid, budding yeast cells in pus exudate from granulomas and other clinical materials.

The *duboisii* variety of *H. capsulatum* can be readily isolated from clinical material on a variety of media. In its mycelial form grown at 25°C, the isolates cannot be distinguished from the *capsulatum* variety as stated previously. Only by converting the mycelial isolates to their yeast form at 37°C on blood or brain–heart infusion agars can the *duboisii* variety be identified. The diagnostic large-form unicellular cells (12–15 μm in diameter) are formed in significant numbers only in cultures held for several weeks at 37°C.

It has long been surmised that the *duboisii* variety was geophilic, but its isolation from soil was not achieved until 1994. In that year, Gugnani et al. reported the first isolation of that variety from eight of 45 soil specimens collected in an eastern Nigerian bat cave in the state of Anambra. It is noteworthy that one of the eight isolates was recovered by direct plating of a 10^{-5} dilution of a soil suspension on an unspecified agar plate (either Sabouraud's dextrose agar or yeast extract agar supplemented with antibiotics).

In addition, the duboisii variety was recovered from the intestinal contents of one of 35 bats comprising the species *Nycteris hispida* – the hairy slit-faced bat – and *Tadarida* (*Chaerephora*) *pumila* – the lesser mastiff bat. The positive bat was one of the hairy slit-faced bats that are found in most of Africa south of the Sahara (Nowak 1991). Thus, another nonhuman mammalian host of this variety has been added to those previously known: *Papio cynocephalus cynocephalus* – the yellow baboon (Curtois et al. 1955); *Papio cynocephalus anubis* – the olive baboon (Butler and Hubbard 1991); and *Papio cynocephalus papio* – the red baboon (Walker and Spooner 1960).

In a personal communication from P.K.C. Austwick (August 1980), one of us (L.A.) was informed that two aardvarks (*Oryceteropus capensis*), one in the London Zoo and another in the Copenhagen Zoo, were histologically confirmed to have lungs infected by *H. duboisii*. The aforementioned baboons and bat, as well as the soil burrowing aardvarks, may act and serve as sentinels for the presence of the *duboisii* variety in a

given territory. This would parallel the role played by badgers (*Meles meles*) in Denmark (Jansen et al. 1992), Germany (Rapp et al. 1992; Grosse et al. 1997), and Switzerland (Burgisser et al. 1961) in revealing endemic foci of the *capsulatum* variety of *H. capsulatum* in these respective countries.

An epizootic of histoplasmosis duboisii in a Texan colony of 3 400 baboons casts a new light on the epidemiology of this disease (Butler et al. 1988; Butler and Hubbard 1991). Twenty-one cases of simian histoplasmosis duboisii developed over a period of 4 years in the primate colony in San Antonio, TX. Eight of the baboons had been born in the USA whereas of 13 wild-caught simians, six (*P. cynocephalus papio*) had been imported from Senegal, a west African country known to be endemic for *H. capsulatum* var. *duboisii*, and the remaining seven (four *P. cynocephalus cynocephalus* and three *P. cynocephalus anubis*) had been captured in Kenya, an east African country with no known endemic cases of histoplasmosis duboisii. The first infection was diagnosed in one of the Senegalese baboons, 18 months after entry into the USA. The Kenyan baboons developed their infections 10–12 years after being colonized in Texas.

In their 1991 report, Butler and Hubbard stated that the incubation period in their baboons was at least 9 months with a possible upper-end incubation period of 18 months. The most likely route of transmission from the Senegalese import was a direct contact brought about by the grooming habits of the baboons. This social habit involves licking of lesions or picking and ingesting material from lesions on other animals.

In humans, however, in analogy with the *capsulatum* variety, histoplasmosis duboisii is acquired via the respiratory route (Gatti and DeVroey 1991) and, as revealed by Gugnani et al. (1994), soil is the natural habitat occupied by this etiologic agent.

Histoplasma capsulatum var. *farciminosum* (Rivolta 1873) Weeks, Padhye et Ajello 1985

The *farciminosum* variety of *H. capsulatum* has the distinction of having been the first of the three varieties to have come to medical attention and to have been identified as the etiologic agent of a widespread endemic disease known variously as the farcy of Africa, the farcy of Naples and, most commonly, epizootic lymphangitis.

The disease had long been confused with glanders, a highly contagious disease of asses, horses, and mules caused by *Pseudomonas mallei*. In 1873, Rivolta of Pisa, Italy, noted the presence of yeast-like organisms in clinical material taken from horses suffering from epizootic lymphangitis, which he considered to be a species of *Cryptococcus*. The yeast cells noted in the pus taken from the lymph nodes of a horse were unicellular, oval, and budding. In size, these cells measured 2.5–3.5×2.3 μm. Ten years later in 1883, he and Micellone named the organism *C. farciminosum* (Rivolta and Micellone 1883). However, it was not until 1895 that this organism was successfully isolated and cultured by Marcone of Naples. The isolate developed as a sterile mold in a medium composed of horse serum, glucose, glycerin, and sucrose (Marcone 1895).

It remained for Redaelli and Ciferri to recognize that the agent of epizootic lymphangitis was a dimorphic mold and that it was appropriate to transfer the organism to Darling's genus *Histoplasma* on the basis that in tissues the in vivo form cells of *C. farciminosum* were indistinguishable from those of the *capsulatum* variety of *H. capsulatum*. They accordingly transferred Rivolta's *C. farciminosum* to the genus *Histoplasma* as *H. farciminosum* (Ciferri and Redaelli 1934).

In 1985, in studying Egyptian isolates from horses, Weeks et al. induced the production of numerous microconidia and moderate numbers of tuberculate macroconidia. This was accomplished by incubating the cultures in the dark at 30°C for a period of 8–12 weeks on soil-extract agar. The smooth to rough-walled microconidia were pyriform to subglobose and measured 3–5×2.5–3.5 μm. The macroconidia were globose to subglobose (8–12×1–1.5 μm) with thick walls. For the first time, these investigators found that the mycelial cultures of *H. farciminosum* produced micro- and macroconidia that are characteristics of the members of the genus *Histoplasma*. In addition, the close resemblance of the yeast forms of the *capsulatum* and *farciminosum* varieties and the antigenic relationship shown to exist between them by Standard and Kaufman (1976) led to the conclusion that *H. farciminosum* was best treated as another variety of *H. capsulatum*.

Unlike the other two varieties of *Histoplasma*, authenticated cases of histoplasmosis farciminosi have only been known to occur in equines: asses (*Equus asinus*), horses (*E. caballus*), and mules (*E. asinus* × *caballus*). It is pertinent to note that only in the African continent do the three varieties of *H. capsulatum* coexist.

HOST RESPONSE

Human infection with *H. capsulatum* var. *capsulatum* is usually clinically unrecognized, identified only by skin test positivity or pulmonary or splenic calcifications. Symptomatic cases present with a variety of clinical manifestations ranging from an acute pulmonary disease, to a chronic pulmonary infection, or a progressive disseminated form. Among symptomatic cases with no underlying lung disease or immunosuppressive disorders, self-limiting illnesses develop in more than 90 percent of individuals. Chronic pulmonary histoplasmosis develops in those with underlying emphysema, and progressive disseminated disease in those at the extremes of age or

who are immunosuppressed. In this section the main clinical manifestations of histoplasmosis capsulati are examined.

Clinical forms

ACUTE SELF-LIMITED HISTOPLASMOSIS CAPSULATI

After low-inoculum exposure, the infection is asymptomatic in at least 90 percent of cases (Wheat and Kauffman 2003). Among symptomatic patients, the most common clinical presentation is acute pulmonary histoplasmosis characterized by fever, cough, and chest pain. Chest x-rays show mediastinal lymphadenopathy with infiltrates (Figure 1). Most patients recover in a few weeks, but some experience prolonged fatigue. Heavy exposure causes diffuse pulmonary involvement, which is often accompanied by respiratory failure (Kataria et al. 1981). Patients may also experience symptoms as a result of compression of the mediastinal structures by enlarged lymph nodes (Loyd et al. 1988). Patients with acute histoplasmosis may experience rheumatological syndromes characterized by arthritis or arthralgia, and erythema nodosum or erythema multiforme (Rosenthal et al. 1983). Pericarditis is another inflammatory complication of acute histoplasmosis, and both pericarditis and rheumatological syndromes occur in less than 10 percent of cases (Wheat et al. 1983). Rarely, constrictive pericarditis may develop.

Figure 1 *Chest x-ray showing right hilar lymphadenopathy with adjacent infiltrate in acute pulmonary histoplasmosis capsulati*

CHRONIC PULMONARY HISTOPLASMOSIS CAPSULATI

Chronic pulmonary histoplasmosis capsulati occurs in individuals with underlying bullous lung disease and is characterized by recurrent pulmonary symptoms, progressive lung infiltrates, fibrosis, and cavitation (Figure 2) (Goodwin et al. 1976; Wheat et al. 1984). Most patients experience recurrent illnesses highlighted by progressive radiological worsening and respiratory deterioration. Chest x-rays show cavity enlargement, formation of new cavities, and spread to new areas of the lungs. Rarely, bronchopleural fistula or hematogenous dissemination may develop.

PROGRESSIVE DISSEMINATED HISTOPLASMOSIS CAPSULATI

Hematogenous spread outside the lungs occurs during the acute infection but is rarely recognized clinically. These patients recover with the development of varying degrees of immunity to the *capsulatum* variety of *H. capsulatum*. Progressive disseminated disease occurs in about one in 2 000 acute infections (Sathapatayavongs et al. 1983), mostly in patients who are immunosuppressed or at the extremes of age (younger children and older adults). Common clinical manifestations include fever, weight loss, and respiratory symptoms. Physical examination frequently reveals hepatomegaly and/or splenomegaly. Laboratory tests usually show anemia, leukopenia, thrombocytopenia, and elevated hepatic enzymes and bilirubin. Shock with hepatic, renal, and

Figure 2 *Chest x-ray showing bilateral upper lobe fibrotic infiltrates in a patient with underlying emphysema complicated by chronic pulmonary histoplasmosis capsulati*

respiratory failure and coagulopathy may complicate severe cases (Wheat et al. 1990b). Meningitis, cerebritis, and focal brain or spinal cord lesions occur in 10–20 percent of cases, as either manifestations of widely disseminated infection or isolated findings (Wheat et al. 1990a). Other frequent sites of dissemination include the oral mucosa, gastrointestinal tract, skin, kidneys, and adrenal glands (Figure 3). Endocarditis is a rare manifestation of disseminated histoplasmosis. Chest x-rays usually show diffuse infiltrates but are normal in 25–33 percent of cases (Figure 4).

MEDIASTINAL FIBROSIS

Mediastinal fibrosis represents an abnormal fibrotic response to past infection and is a rare finding (Goodwin et al. 1972; Loyd et al. 1988; Davis et al. 2001). Recurrent hemoptysis is a common symptom and respiratory failure often ensues. Serological tests may be positive and staining of tissues may show the small tissue-form cells of the *capsulatum* variety of *H. capsulatum* in half to two-thirds of cases, although cultures are usually negative, supporting the belief that fibrosing mediastinitis represents an aberrant inflammatory response rather than a progressive infection. The superior vena cava, airways, pulmonary arteries and veins, and the esophagus are most commonly involved, but any mediastinal structure can be trapped in these fibrotic masses (Goodwin et al. 1972; Loyd et al. 1988). Chest x-rays may be normal or show only mediastinal widening, but computed tomography (CT) reveals restriction of mediastinal structures. Pulmonary angiograms may show obstruction of the pulmonary arteries (Figure 5). Calcification is often present. The diagnosis requires demonstration of obstruction of mediastinal structures by CT scan, and cannot be made based on the presence of fibrosis histopathologically in biopsy specimens, as this finding is not specific for fibrosing mediastinitis.

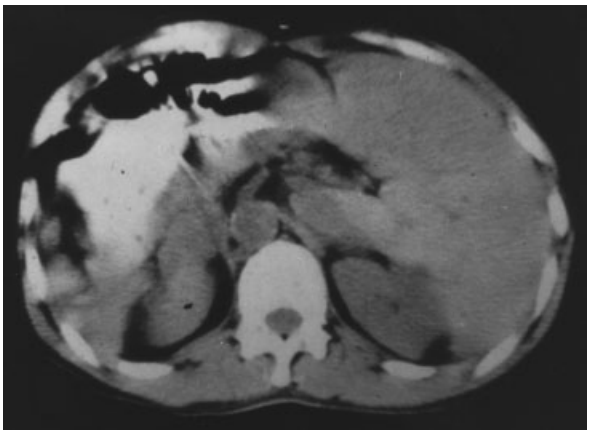

Figure 3 *Bilateral adrenal enlargement caused by disseminated histoplasmosis established by fine needle aspiration biopsy showing organisms consistent with* H. capsulatum *var.* capsulatum

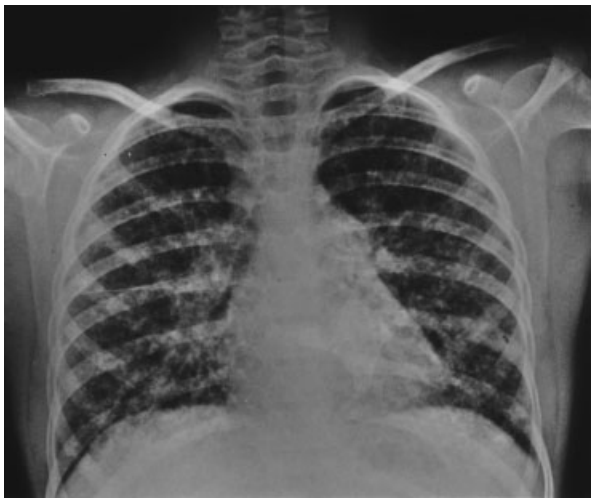

Figure 4 *Chest x-ray showing diffuse miliary infiltrate in a patient with disseminated histoplasmosis capsulati*

HISTOPLASMOMA AND BRONCHOLITHIASIS

Rarely, patients may develop a slowly enlarging pulmonary nodule, which has been called an 'enlarging histoplasmoma' (Goodwin and Snell 1969), causing concern about neoplasia. Lesions range in diameter from 8 to 35 mm and enlarge slowly (2 mm/year). Histologically, they are characterized by a necrotic center surrounded by a fibrous-like capsule. Organisms may be seen in the necrotic center but usually cannot be isolated

Figure 5 *Pulmonary angiogram showing obstruction of right pulmonary artery in a patient with fibrosing mediastinitis*

in culture. As these lesions or mediastinal nodes calcify, they may erode into adjacent bronchi, causing broncholithiasis (Arrigoni et al. 1971). Patients may experience recurrent hemoptysis and expectorate small gravel-like particles of tissue. Bronchial obstruction or tracheoesophageal fistula may also complicate broncholithiasis.

PRESUMED OCULAR HISTOPLASMOSIS CAPSULATI

This distinct clinical entity is usually seen in histoplasmin skin test-positive individuals residing in endemic areas for histoplasmosis capsulati, but scientific evidence that *H. capsulatum* var. *capsulatum* causes this syndrome is not very convincing (Spaeth 1971; Ciulla et al. 2001). However, the eye may also be involved in patients with disseminated histoplasmosis (Specht et al. 1991). Ocular histoplasmosis and presumed ocular histoplasmosis are discussed in Oculomycosis.

Immunology

Histoplasma capsulatum var. *capsulatum* can be a primary pathogen producing systemic disease in normal individuals or opportunistic infection in immunocompromised hosts. The infection is acquired by inhalation of the infectious propagules of *H. capsulatum* into the respiratory tract. The conversion from mycelial to yeast form is critical because it is the yeast form in which *H. capsulatum* var. *capsulatum* exists as a facultative intracellular parasite of the mononuclear cells in the susceptible host (Schwarz 1981). The virulence factor(s) and the mechanisms(s) by which *H. capsulatum* causes disease are not clearly defined. The disease process may involve an endotoxin-like substance (Salvin 1952), collagenases and elastases (Okeke and Miller 1991), siderophores (Burt 1982), and immunological mechanisms: complement-mediated/hypersensitivity and cytokines may contribute to pathogenesis (review by Howard 1981a; Lane et al. 1994; Zhou et al. 1995). In addition, the ability of live *H. capsulatum* var. *capsulatum* yeast cells to neutralize the acidic environment (pH 5.0) of phagolysosomes, enabling them to survive within macrophages, contributes to the virulence of the organism (Eissenberg et al. 1993). The host's ability successfully to mount a series of complex but interrelated cellular responses in the lung is responsible for the recovery and possible development of resistance to reinfection. The cells of the immune system 'talk' to each other by direct cell–cell interactions, cytokine production, and associated signal transduction. The salient features of the natural (innate) and acquired immunity are discussed in the next section.

NATURAL (INNATE) IMMUNITY

Although the precise initial events in the interaction between the previously uninfected host and infective conidia are not well defined, the innate cellular resistance to histoplasmosis capsulati is mediated by polymorphonuclear leukocytes (PML), macrophages, and natural killer (NK) cells. The inhaled infectious units (conidia and mycelial fragments) of *H. capsulatum* var. *capsulatum* lodge within the terminal bronchioles and alveoli. The organism changes from mycelial to yeast-form cells, the form in which the *capsulatum* variety of *H. capsulatum* exists as a facultative intracellular parasite in the susceptible host (Schwarz 1981). The initial cellular infiltrate is composed predominantly of PMLs, which changes to a predominance of macrophages and lymphocytes with progression of the inflammatory response. The microconidia and yeast cells of the invading pathogen bind to the PMLs via the CD11/CD18 family of integrins (adhesion-promoting glycoproteins) without prior opsonization (Schnur and Newman 1990). After binding, the ingestion of *H. capsulatum* var. *capsulatum* is rapid and maximum phagocytosis occurs within 1 hour. The PMLs from guinea pigs and mice exhibit significant fungicidal activity to both the conidia and yeast cells of *H. capsulatum* in vitro (review by Howard 1981a; Kondoh et al. 1989). The killing of conidia and yeast cells is mediated by the combined effect of hydrogen peroxide, halides, and myeloperoxidase (Howard 1981b).

Although there is some controversy regarding their fungicidal activity, human PMLs exert strong fungistasis against the *capsulatum* variety of *H. capsulatum* (Schnur and Newman 1990; Brummer et al. 1991). Phagocytosis of opsonized yeast cells by PMLs stimulates the respiratory burst with intracellular production of H_2O_2 and O_2^-. This phenomenon appears to be unique to PML–*H. capsulatum* interaction, because O_2^- is not released by monocytes upon phagocytosis of the yeast cells. These findings suggest that PMLs may be more important in early host defenses against *H. capsulatum* than previously recognized.

Normal macrophages recognize, bind, and phagocytose *H. capsulatum* conidia and yeast cells, thereby providing a permissive environment for multiplication of the organism in the yeast form (Figure 6). The yeast cells attach to human macrophages via the CD11/CD18 family of integrins – the same receptors by which they bind to PMLs (Schnur and Newman 1990). Once ingested, the *capsulatum* variety of *H.capsulatum* yeast cells confront a hostile environment, which occurs by stimulation of the respiratory burst and phagolysosomal fusion, although the yeast cells survive and grow within normal human and murine macrophages (Figure 6). How *H. capsulatum* survives within macrophages is not known. However, the ability of live yeast cells to neutralize the acidic environment (pH 5.0) required for the fungicidal activity of many lysosomal enzymes has been suggested as a possible mechanism (Eissenberg et al. 1993).

There is considerable evidence to indicate that NK cells participate in early host defenses against *H. capsulatum*. var. *capsulatum*. NK cells from lungs and spleens

of normal mice are cytotoxic to *H. capsulatum* yeast cells in vitro (Yamada et al. 1982; Raman et al. 1989b). The cytotoxicity is enhanced by addition of anti-histoplasma antibody to NK cell–yeast cell cultures, demonstrating antibody-dependent cellular cytotoxicity (ADCC) by NK cells to *H. capsulatum*. Likewise, NK cells isolated from human peripheral blood of both histoplasmin-positive and histoplasmin-negative subjects exhibit natural as well as ADCC to *H. capsulatum* (Tewari et al. 1981; Choudhury et al. 1989). Although the mechanism of NK cell cytotoxicity is not known, the NK cells bind to *H. capsulatum* by microvilli (Figure 7), in a similar way to that previously described for binding of NK cells to tumor cell targets (Frey et al. 1982). The binding is followed by exocytosis of NK cell granules and the cytotoxicity is presumably expressed by associated signal transduction.

Additional evidence for involvement of NK cells in innate resistance to histoplasmosis capsulati is provided by NK cell depletion and adoptive transfer experiments. Depletion of NK cells by administration of anti-NK cell antibody (anti-asialo GM1) enhanced susceptibility of mice to histoplasmosis as assessed by challenge with *H. capsulatum* yeast cells. (Raman et al. 1989a). Furthermore, adoptive transfer of NK cells to cyclophosphamide-treated mice (NK cell deficient) restored the in vitro NK cell activity of their lung and spleen cells and protected them from a subsequent challenge with *H. capsulatum* (Raman et al. 1990).

The yeast-form cells of *H. capsulatum* var. *capsulatum* have a predilection for the reticuloendothelial system and, in fact, the term 'reticuloendotheliosis' was formerly used as a synonym for histoplasmosis capsulati. It is noteworthy that yeast cells were seen in the endothelial cells lining blood and lymph vessels and in alveolar lining of the lungs by Darling (1906), in the first reported human case of histoplasmosis in Panama (review by Schwarz 1981). In an attempt to elucidate the mechanism involved in extrapulmonary dissemination of the organism, an in vitro experimental model has been developed to study the interaction of *H. capsulatum* var. *capsulatum* with human umbilical vein endothelial cells,

mouse pulmonary cells, and mouse heart endothelial cells, in monolayer cell cultures (Bedrosian et al. 1986; Tewari et al. 1986; Hughes et al. 1994). The endothelial cells maintain a cobblestone arrangement and other characteristics described for endothelial cells, but are much larger than macrophages. Both human and mouse endothelial cells adhere to, phagocytose, and kill yeast cells of *H. capsulatum* (Figure 8). Unlike macrophages, where maximum phagocytosis is observed within 1 hour, optimum endothelial cell phagocytosis requires 4–6 hours. However, only 25–30 percent of cells in monolayer cultures react with *H. capsulatum*, suggesting a heterogeneous nature for endothelial cells. Ultrastructural studies provide supporting evidence for morphological degradation and killing of yeast cells (Figure 8). These findings indicate that endothelial cells may have a critical role in host defenses to histoplasmosis capsulati.

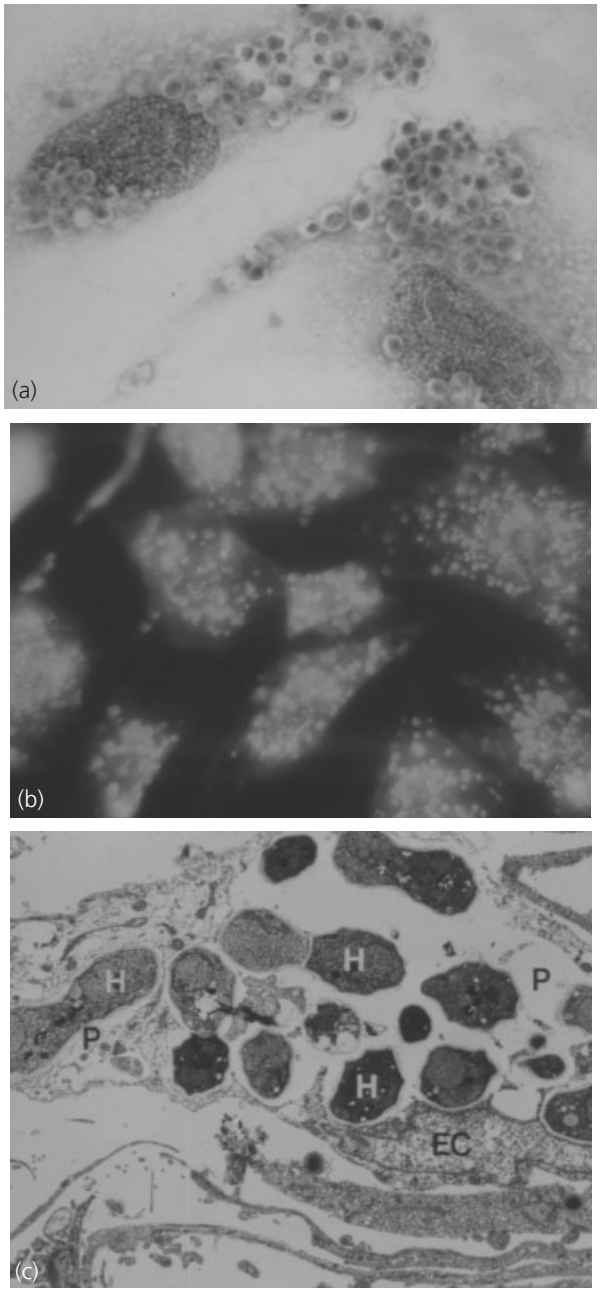
The role of humoral factors in natural resistance to histoplasmosis is not clearly defined. Nevertheless, heat-labile and/or heat-stable serum opsonins enhance phagocytosis of *H. capsulatum* var. *capsulatum* yeast cells by PMLs, but not by macrophages (review by Deepe and Bullock 1992). Furthermore, normal serum inhibits growth of *H. capsulatum* yeast cells and the inhibition is attributed to transferrin, which binds iron and makes it unavailable for nutritional requirement of the organism (Sutcliffe et al. 1980).

ACQUIRED IMMUNITY

H. capsulatum var. *capsulatum* is a highly immunogenic mold and acquired immunity is expressed by induction of a spectrum of cellular as well as humoral immune responses. However, it is generally accepted that the primary host defense mechanism activated in response to *H. capsulatum* is the cell-mediated arm of the immune response. Several lines of evidence support this concept:

- Congenitally athymic (nude) mice lacking T cells are more susceptible to *H. capsulatum* var. *capsulatum* infection (Williams et al. 1978; Miyaji et al. 1981).
- Lymphokines from immune mice or IFN-γ can activate macrophages for enhanced antifungal activity to *H. capsulatum* (Wu-Hsieh and Howard 1984, 1987).
- Adoptive transfer of T cells but not B cells or serum from immunized mice protects naive animals against a lethal challenge with *H. capsulatum* (Tewari et al. 1977, 1978; Williams et al. 1981).
- Transfer of *H. capsulatum*-reactive CD4 cells and to a lesser extent that of CD8 cells confers immunity to naive mice against histoplasma yeast cells (Allendoerfer et al. 1993; Deepe 1994).
- Immunized mice exhibit a delayed-type hypersensitivity (DTH) response to histoplasmin, and lymphocytes proliferate in response to histoplasmin in culture (Tewari et al. 1982; Khardori et al. 1986; Sharma et al. 1986).

How T cells contribute to protective immunity is not well understood. The most logical mechanism by which T cells augment the protective immune response is by release of macrophage-activating lymphokines which, in turn, arm the macrophages for more efficient antifungal activity. Although T cells can produce a number of regulatory cytokines, IFN-γ is the only cytokine that has been shown to arm murine macrophages for antifungal activity against *H. capsulatum* (Wu-Hsieh and Howard 1987). Abrogation of protective immunity by administration of anti-IFN-γ antibody to mice (Zhou et al. 1995) and failure of IFN-γ to knock out mice to control *H. capsulatum* infection (Wu-Hsieh and Howard 1984) further support the role of IFN-γ in histoplasmosis capsulati. In addition to CD4 cells, CD8 and NK cells produce IFN-γ and thus could potentially produce IFN-γ in *H. capsulatum* infection. However, co-culturing of human monocyte-derived macrophages with IFN-γ does not enhance their anti-*H. capsulatum* activity (Fleishmann et al. 1990), but they are activated by interleukin 3 (IL-3), granulocyte–macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF) (Newman and



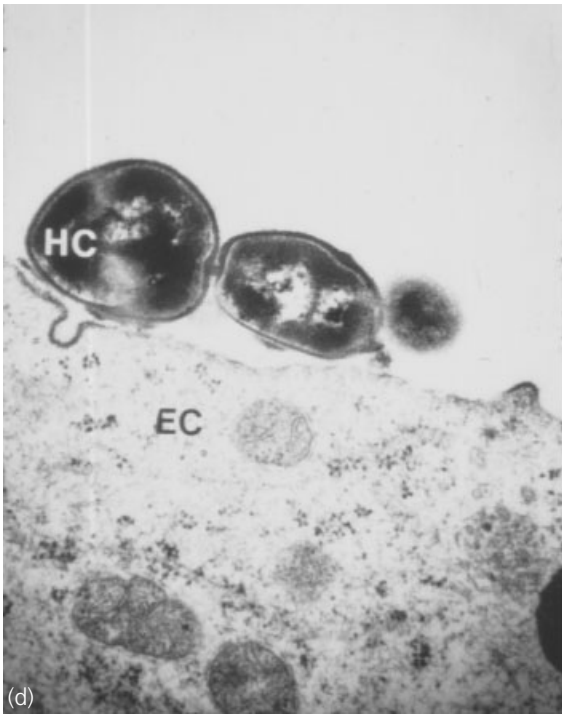


Figure 8 *Interaction of human umbilical cord endothelial cells (EC) with* H. capsulatum *var.* capsulatum *(HCH) in culture.* **(a)** *An endothelial cell monolayer, 4 hours after incubation with histoplasma yeast cells. Gootee 1992), indicating differences in signaling mechanisms for macrophage activation between the two species.

Administration of interleukin 12 (IL-12) or neutralizing antibody to interleukin 4 (IL-4) has a protective effect on *H. capsulatum* infection in mice, demonstrating the antagonistic role of these cytokines (Zhou et al. 1995). Treatment of *H. capsulatum*-infected mice with neutralizing antibodies to IL-12, IFN-γ or tumor necrosis factor α (TNF-α), enhances the severity of the disease. Recently treatment with tumor necrosis factor (TNF) inhibitors has been shown to predispose to severe histoplasmosis in man (Wood et al. 2003). Moreover, IL-12 treatment increases the endogenous production of IFN-γ in infected mice, suggesting that the protective effect of IL-12 is primarily mediated through production of IFN-γ. Recently, Zhou et al. (1997) also demonstrated the protective effect of IL-12 against histoplasmosis capsulati in immunodeficient severe combined immunodeficiency disease (SCID) mice. The effect was further increased by combining IL-12 with amphotericin B. The protective effect is associated with increased production of IFN-γ, TNF-α, and nitric oxide from spleen cells.

Macrophages from immunized mice or macrophages activated in vitro have ruffled membranes with high affinity surface receptors and are far more phagocytic than normal macrophages (see Figure 6). The activated macrophages also have more lysosomal enzymes and the ability to produce more reactive nitrogen and oxygen intermediates (RNI-NO, NO_2^-, and ROI-H_2O_2, O_2^-). However, it is generally considered that activated macrophages exert fungistatic but not fungicidal activity against the *capsulatum* variety of *H. capsulatum*,

although ultrastructural studies indicate morphological degradation of the ingested organisms. Neutralization of the acidic environment of phagolysosomes (pH 5.0) has been proposed as a possible mechanism for survival of *H. capsulatum* within macrophages (Eissenberg et al. 1993).

The opsonization of microconidia and yeast cells with anti-*H. capsulatum* antibodies increases the phagocytic activity of PMLs, but the enhancing effect of antibodies is not observed in phagocytosis of the organism by macrophages (review by Deepe and Bullock 1992). The antibody-dependent cellular cytotoxicity of both murine and human NK cells to *H. capsulatum* yeast cells, and thus antibodies, may have a contributory role in host defenses (Tewari et al. 1982; Choudhury et al. 1989).

The inhalation of a small number of *H. capsulatum* conidia, which frequently occurs in individuals living in an endemic area for histoplasmosis capsulati, results in asymptomatic or mild self-limiting infections with concomitant development of resistance to reinfection. This had also been observed in experimental animals in the early 1950s and provided the major rationale for development of a vaccine for histoplasmosis (review by Salvin 1965). The immunity induced by sublethal infection of experimental animals persisted longer than that induced by killed organisms or fractions thereof. However, only a low level of protection was observed in mice immunized with killed cells and the immunogenicity was attributed to cell wall constituents. Feit and Tewari (1974) demonstrated that immunization of mice with *H. capsulatum* yeast ribosomes or ribosomal proteins elicited a high degree of immunity, protecting up to 90 percent of animals from a lethal challenge. The immunity was comparable to that obtained by a sublethal infection with live yeast cells (Tewari 1975). Furthermore, a cytoplasmic membrane fraction or membrane proteins were as immunogenic as ribosomes (Tewari and LaFemina 1983; Tewari et al. 1989). Recently, Deepe and his associates isolated a glycoprotein (HIS-62) from the cell walls and cell membranes of *H. capsulatum* var. *capsulatum* yeast cells, cloned the gene encoding this antigen, and prepared a recombinant protein that was shown to be a member of the heat-shock protein Hsp60 family. Immunization of mice with the native as well as with the recombinant protein conferred significant protection against a lethal challenge with *H. capsulatum* yeast cells (Gomez et al. 1991, 1995). However, another protein (80 kDa) from *H. capsulatum* var. *capsulatum* with homology to Hsp70 did not provide significant protection. In view of the concern of using heat-shock proteins as a vaccine in humans, four recombinant polypeptides were prepared from Hsp60, but these recombinants did not confer significant protection against histoplasmosis capsulati (Deepe et al. 1996).

There is a strong correlation between protective immunity and delayed hypersensitivity in histoplasmosis. Lymphocytes from immunized mice proliferate in response to histoplasmin and the proliferative response is used as an in vitro correlate of DTH responses (Tewari et al. 1982; Deepe et al. 1996). Furthermore, there is a strong correlation between footpad reactivity (DTH reaction) to histoplasmin and production of macrophage migration inhibition factor (MIF) when peritoneal exudate cells from immunized mice are cultured with histoplasmin (Tewari et al. 1989). It is noteworthy that both the DTH reaction and MIF production decayed faster than the protective immunity in immunized mice. The immunized mice showed footpad reactivity (DTH) responses to histoplasmin which peaked between 21 and 28 days after immunization, and thereafter showed a gradual decline, reaching the control level at 105 days (Khardori et al. 1986; Sharma et al. 1986). There was, however, no decline in protective immunity for up to 105 days, the maximum observation period used in these studies (Figure 9). It is noteworthy that protective immunity persisted longer than the DTH reaction and MIF production, demonstrating a dichotomy between the two manifestations of the immune response in histoplasmosis capsulati.

Treatment

Histoplasmosis capsulati is a systemic fungal infection with a wide spectrum of clinical manifestations in different individuals. The therapy of the disease has to be clinically determined after taking into consideration the immunocompetence of the host, site of infection, and the extent of the disease. Initially, amphotericin B was the only effective drug available for treatment. However, toxicity of the drug limited its use to patients with severe disease. The development of azoles such as ketoconazole and, more recently, itraconazole, which have lower toxicity and can be given orally, has allowed the clinician options for treatment of patients with less severe disease. The current recommendations for treatment are presented in this section.

ACUTE PULMONARY

Patients with extensive acute pulmonary histoplasmosis capsulati benefit from antifungal therapy and those who are hypoxic may also require adjunctive corticosteroid therapy (Table 1) (Wheat and Kauffman 2003). Patients with less extensive disease but who remain symptomatic for a month or more may also benefit from therapy. While the benefit of therapy for patients with more severe, diffuse disease seems to be clear, based upon the author's experience and the anecdotal reports of others, the effect in patients with localized disease and persistent symptoms is uncertain. Amphotericin B should be used in severely ill patients requiring hospitalization (Table 2). Itraconazole is highly effective in individuals with milder illnesses or as a follow-up

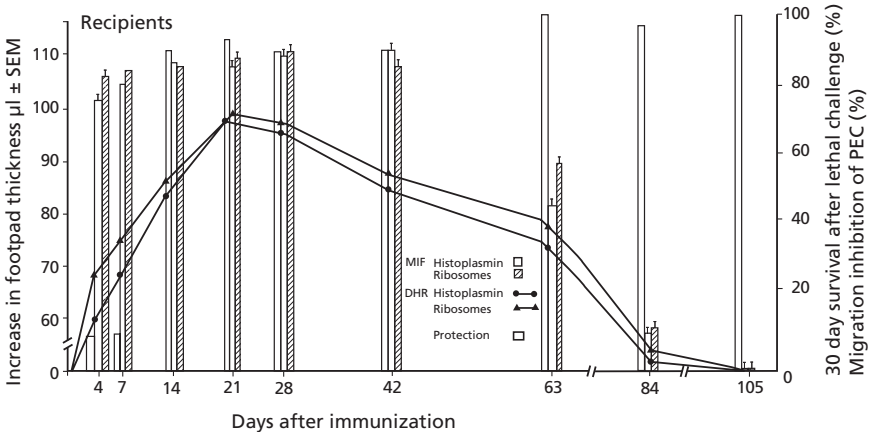

Figure 9 *Relationship of protective immunity, footpad reactivity, and production of macrophage MIF by peritoneal exudate cells from mice immunized by sublethal infection with yeast cells of* H. capsulatum *var.* capsulatum *(105 cells, s.c.). Mean ± SEM of five mice per time period for delayed hypersensitivity and MIF and 20 mice per group for protective immunity (10 mice/group per experiment)*

therapy after an initial response to amphotericin B (Wheat et al. 1995).

MEDIASTINAL GRANULOMA

Mediastinal granuloma may produce obstructive symptoms or fistula. Occasional patients with these complications improve after antifungal therapy (Savides et al. 1995), but some may require surgical resection (Gilliland et al. 1984). The benefit of therapy in such cases, however, is difficult to prove. Prophylactic antifungal therapy or surgery to prevent fibrosing mediastinitis is not indicated because progression of granulomatous to fibrosing mediastinitis is rare (Loyd et al. 1988).

RHEUMATOLOGICAL AND PERICARDITIS

Patients with these inflammatory manifestations may respond to aspirin or nonsteroidal anti-inflammatory agents, but also may require treatment with corticosteroids (Rosenthal et al. 1983; Wheat et al. 1983). Antifungal therapy is not required, but should be considered in those receiving corticosteroids at higher than physiological doses for more than 3 weeks, in order to reduce the risk for dissemination during corticosteroid-induced immunosuppression. Rarely, joints and the pericardium are sites of disseminated infection, in which case treatment would be necessary.

Table 1 *Summary of indications for treatment of histoplasmosis capsulati*

Treatment indicated	Treatment not indicated
Acute pulmonary, diffuse	Pericarditis
Acute pulmonary, localized with prolonged symptoms	Rheumatological
Chronic pulmonary	Fibrosing mediastinitis
Disseminated	Histoplasmoma
Symptomatic mediastinal granuloma	Presumed ocular histoplasmosis

CHRONIC PULMONARY

Treatment of chronic pulmonary histoplasmosis capsulati improves survival, reduces symptoms, promotes radiological healing, and eradicates *H. capsulatum* from the sputum (Sutliff et al. 1964). Most patients (about 80 percent) respond well to itraconazole 200–400 mg daily (Dismukes et al. 1992). Itraconazole should be continued for at least a year and until maximal clinical and radiological benefits have been achieved. Amphotericin B may be needed initially in patients with severe respiratory insufficiency. Relapse is common (about 25 percent) after discontinuation of treatment, emphasizing the need for prolonged follow-up.

DISSEMINATED

Disseminated histoplasmosis is usually fatal if untreated (Furcolow 1963; Sathapatayavongs et al. 1983). Liposomal amphotericin B induced a more rapid response than the standard deoxycholate formulation, and improved survival in patients with the acquired immunodeficiency syndrome (AIDS) (Johnson et al. 2002). The high cost of the liposomal formulation may preclude its use in all situations, however. Amphotericin B and itraconazole induce a favorable response in 85–90 percent of patients (Wheat et al. 1990b, 1995; Dismukes et al. 1992). Itraconazole should be administered for at least a year in most patients. Relapse is common in patients who are immunosuppressed, including those with AIDS. The level of histoplasma antigen declines during therapy and increases with relapse, providing a useful tool for monitoring the response to therapy (Wheat et al. 1991). Treatment should be continued until antigenemia and antigenuria have resolved or at least reached a stable low level (<2 units). Lifelong maintenance treatment is needed in patients with AIDS who do not achieve a good CD4 cell response to potent antiretroviral therapy. If the CD4 cell count increases to

Table 2 *Recommendations for antifungal therapy of histoplasmosis capsulati*

Disease severity	Drug	Dose	Duration
Mild	Itraconazole	200 mg t.i.d. × 3 days or 200 mg q.d or b.i.d.[a]	3–24 months[b]
Moderate or severe	Amphotericin B or liposomal amphotericin B	0.7–1 mg/kg/day or 3 mg/kg/day for liposomal preparation	3 days to 2 weeks based on severity[c]

a) The itraconazole dose should begin as a loading dose followed by a treatment dose of 200 mg once or twice daily. Blood levels should be measured after 1 week of therapy and the dosage should be modified to maintain blood levels between 1 and 10 μg/ml.
b) Treatment duration ranges from 3 months in patients with acute pulmonary histoplasmosis to 12–24 months in patients with disseminated or chronic pulmonary histoplasmosis. If treatment is initiated with an amphotericin B formulation, itraconazole may be used to complete the recommended duration of therapy. Patients with AIDS may require lifelong treatment if they fail to achieve CD4 cell improvement to >150 cells/ml in response to potent combination antiretroviral therapy.
c) Amphotericin B dosage is 0.7–1 mg/kg/day whereas the dosage of the liposomal preparation is 3 mg/kg/day.

150 cells/mm^3 or higher, and the antigen levels in urine and serum decline to <2 units, itraconazole may be stopped after one year. Maintenance therapy also may be required in other immunocompromised individuals with persistent immunosuppression, or those who have relapsed after extended courses of amphotericin B or itraconazole.

The response to therapy in patients with meningitis is inferior to that in other types of histoplasmosis: 20–40 percent of patients with meningitis die and up to half of responders relapse after therapy is stopped. The optimal treatment for *Histoplasma* meningitis is unknown, but an aggressive approach is recommended because of the poor outcome. Although the best therapy is still not known, it seems reasonable to begin therapy with liposomal amphotericin B, 3–5 mg/kg/day, for 2–3 months and until CSF cultures are negative and CSF antigen levels are negative, followed by itraconazole, 200 mg twice or three times daily for at least another year. Lifelong maintenance therapy may be needed in patients who relapse or in those whose CSF findings do not return to normal. Patients who fail chronic itraconazole therapy have these options: fluconazole 800 mg daily, voriconazole 200 mg twice daily, and posaconazole.

MEDIASTINAL FIBROSIS

Antifungal treatment usually does not influence the course of mediastinal fibrosis (Goodwin et al. 1972; Loyd et al. 1988; Davis et al. 2001). However, a few patients have shown improvement after treatment with ketoconazole (Urschel et al. 1990). In such cases, differentiation between fibrosing and granulomatous mediastinitis may have been difficult. Thus, a 3-month trial of itraconazole is reasonable, especially in patients with positive serological tests and elevated erythrocyte sedimentation rates, or findings that may be more consistent with granulomatous mediastinitis. It is not likely to be helpful, however, since the pathogenesis is fibrosis rather than infection or inflammation. Resection of the fibrotic tissue may be helpful but has a high operative mortality (about 25 percent) and probably should be reserved for patients with severe and progressive manifestations (Mathisen and Grillo 1992). A nonprogressive course is common, precluding the need for surgical intervention (Goodwin et al. 1972; Loyd et al. 1988).

PRESUMED OCULAR HISTOPLASMOSIS CAPSULATI

Presumed ocular histoplasmosis does not represent an active infection and would not be expected to respond to antifungal therapy, although no prospective trials have been reported (Ciulla et al. 2001).

LABORATORY DIAGNOSIS

Direct examination

Rounded to oval yeast cells measuring 2–4 mm in diameter, characteristic of *H. capsulatum* var. *capsulatum*, may be seen by fungal staining of biopsy specimens from pulmonary, mediastinal, or extrapulmonary tissues. Less commonly, organisms may be observed by fungal staining of sputum, sterile body fluids, or peripheral blood smears. In disseminated histoplasmosis capsulati, the highest yield is from bone marrow (>50 percent) (Figure 10). Organisms may be overlooked in patients with histoplasmosis leading to false-negative results, and staining artefacts or other organisms may be mistaken for *H. capsulatum* in patients with other diseases, emphasizing the importance of the skill and experience of the examiner for accurate interpretation of fungal stains. *Candida (Torulopsis) glabrata*, *Blastomyces dermatitidis*, capsule-deficient strains of *Cryptococcus neoformans*, *Penicillium marneffii*, *Toxoplasma gondii*, and *Pneumocystis carinii* may be misidentified in routine clinical laboratories as the tissue-form cells of the *capsulatum* variety of *H. capsulatum*. Mucicarmine staining for capsular material may be used to distinguish *C. neoformans* from *H. capsulatum*, but capsule-deficient strains may be misidentified by this technique. In such cases, melanin staining is positive with *C. neoformans* but negative with *H. capsulatum*.

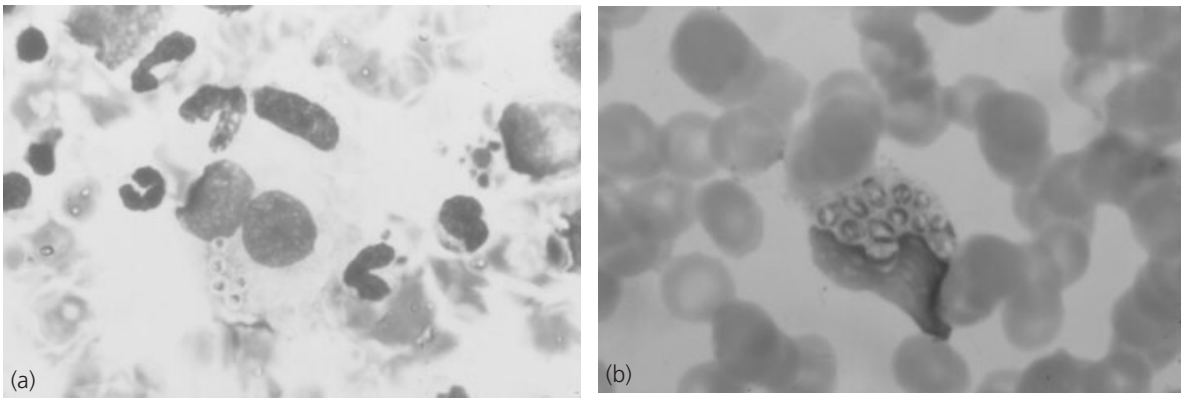

Figure 10 (a) *Bone marrow smear from a young girl with disseminated histoplasmosis capsulati showing budding yeast cells (2–4 μm) in a phagocytic monocyte Giemsa stain; magnification ×3 400).* **(b)** *Peripheral blood smear of an AIDS patient with disseminated histoplasmosis capsulati showing numerous yeast cells (2–4 μm) in a monocyte (Giemsa stain; ×3 400)*

Culture

Cultures are most useful in patients with disseminated or chronic pulmonary histoplasmosis, being positive in 50–85 percent of cases. In disseminated disease, the highest culture yield is from bone marrow or blood, being positive in over 75 percent of cases (Sathapatayavongs et al. 1983; Wheat et al. 1990b). Organisms can be found in sputum or bronchoscopy specimens from 60–85 percent of patients with cavitary histoplasmosis if multiple specimens are obtained (Wheat et al. 1984). The sensitivity of culture is only 10–15 percent in patients with other forms of histoplasmosis capsulati (Williams et al. 1994). Slow growth (2–4 weeks) may delay the diagnosis in patients with positive cultures (Williams et al. 1994). The development of specific nucleic acid probes has facilitated the identification of *H. capsulatum* var. *capsulatum* in cultures with atypical morphology (Stockman et al. 1993).

Immunoserology

This section will concentrate on three tests that are commonly used: the immunodiffusion and complement fixation tests for detection of antibodies and an immunoassay for demonstration of histoplasma polysaccharide antigen in body fluids. The precipitin bands (H and M) are demonstrated by the immunodiffusion test using histoplasmin as the antigen. H precipitin bands can be demonstrated in less than 25 percent of patients and clear during the first 6 months after infection, whereas M bands appear in about 75 percent of individuals and may persist for several years after the resolution of infection (see Figure 5) (Wheat et al. 1982; Williams et al. 1994). The complement fixation test is performed with both histoplasmin and whole yeast cell antigens. Complement fixation titers of 1:8 or higher are found in most patients with active histoplasmosis capsulati, whereas titers of 1:32 or higher are more suggestive of active infection. Both the immunodiffusion and complement fixation tests should be performed to obtain the highest sensitivity for diagnosis (Figure 11).

Enzyme immunoassay or radioimmunoassay methods for detection of antibodies are more difficult to interpret, because of higher background positivity rates. They have not been validated adequately to recommend their use in place of immunodiffusion and complement fixation methods (Wheat 1993). Antibodies require 4–8 weeks to develop after acute infection and may be negative when the patient is first seen. Furthermore, serological tests may be falsely negative in up to one-third of immunocompromised patients (Williams et al. 1994). False-positive results are caused by antigenic cross reactions with *B. dermatitidis*, *Coccidioides immitis*, and *Paracoccidioides brasiliensis* (Wheat et al. 1986). M precipitin bands and low titers (1:8 or 1:16) of complement-fixing antibodies may require years to clear, causing confusion in patients with other diseases.

Histoplasma polysaccharide antigen is found in the blood, urine, and bronchoalveolar lavage fluid of more than 90 percent of individuals with disseminated histoplasmosis capsulati, and in the urine of 75 percent of those with extensive pneumonitis after heavy acute exposure (Wheat et al. 1986; Wheat and Kauffman 2003). Antigen may be found in the cerebrospinal fluid of 25–50 percent of patients with meningitis caused by histoplasmosis (Figure 11). It is important to recognize that lower levels of crossreactions may be seen in patients with histoplasmosis duboisii, blastomycosis, paracoccidioidomycosis, and penicilliosis marneffei. Antigen levels decline during treatment and increase with relapse, providing a tool for monitoring therapy (Wheat et al. 1991). Antigen levels should be monitored every 3–6 months, and at the time of suspected relapse.

Histoplasmin skin test antigen is a culture filtrate of the mycelial form of *H. capsulatum* var. *capsulatum* but

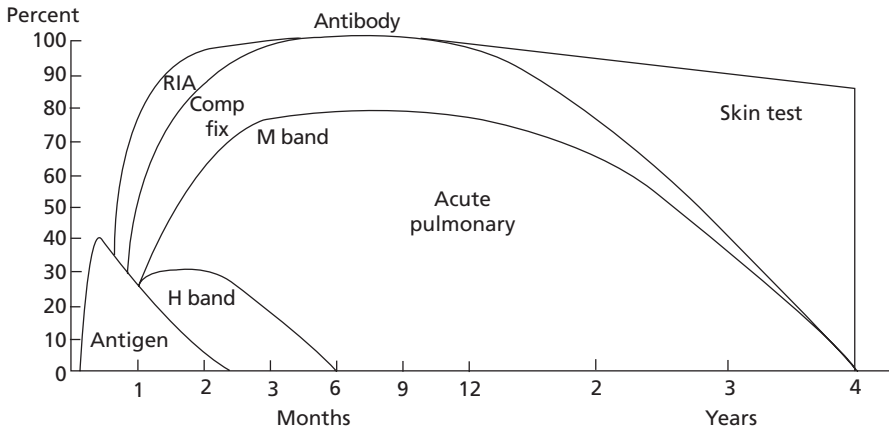

Figure 11 *Time course of diagnostic tests for histoplasmosis capsulati in patients with acute pulmonary disease. Antigen refers to histoplasma antigen in urine. H band and M band refer to precipitants measured by immunodiffusion. Comp fix refers to titers of at least 1:8 to either the yeast or mycelial antigen; Skin test refers to histoplasmin skin test reactivity; RIA refers to measurement of antibodies by radioimmunoassay showing that antibodies may become detectable somewhat earlier than by complement fixation of immunodiffusion.*

is no longer available. Histoplasmin skin testing is not recommended for diagnosis, because of high rates of positivity (50–80 percent) in endemic areas and false-positive results in patients with other fungal diseases (Edwards et al. 1969). Furthermore, skin tests may also be falsely negative in more than half of patients with disseminated disease and skin tests boost the levels of anti-histoplasma antibody, causing confusion in the interpretation of serological tests (Campbell and Hill 1964). The skin test is, however, very useful in epidemiologic studies for determining the prevalence of histoplasmosis capsulati.

Molecular diagnostics

Molecular methods have been developed for diagnosis of histoplasmosis. DNA probes are commercially available and widely used in the clinical mycology laboratory, reducing the time for definitive identification of positive cultures. Research is in progress to develop molecular diagnostic methods to detect *H. capsulatum* var. *capsulatum* DNA in tissue sections and body fluids. To date, while studies suggest that these methods will prove useful, none has been validated by comparison to other established procedures. These are promising methods, particularly for diagnosis of specimens containing granulomas but with negative fungal stains, but require more evaluation before they can be recommended for use in the clinical laboratory. Furthermore, how they will compare with antigen detection in body fluids for rapid diagnosis of histoplasmosis requires further investigation. Nevertheless, polymerase chain reaction (PCR) methods are offered at several commercial laboratories, but should not be accepted as accurate, or used for making the diagnosis of histoplasmosis in patients, until they are validated.

Histopathology

The tissue response in histoplasmosis capsulati follows the general course of histopathological reactions described as granulomas. The early lesions in the lung are areas of pneumonia containing a large number of macrophages and lymphocytes with occasional epithelioid cells and multinucleated giant cells. At this stage, tissue-form yeast cells are easily seen within macrophages. Central areas begin to show necrosis early in the evolution of the lesion, and are occasionally accompanied by transudation of fluid into the necrotic areas (Figure 12). With the progression of the lesion, tissue architecture is lost and its outer margins exhibit epithelioid cells together with multinucleated giant cells, lymphocytes, and plasma cells (Goodwin et al. 1981). Proliferation of fibroblasts, deposition of collagen around margins of the lesion, and calcification are usually observed in old, localized granulomas. In 'histoplasmoma,' the outer portion of fibrosis may consist of multiple layers of fibrous tissue (Goodwin and Snell 1969).

In cavitary pulmonary histoplasmosis capsulati, the cavity lining is necrotic without a well-localized outer margin of fibrosis. Histoplasma yeasts seen in the cavity lining are pleomorphic, with occasional short hyphal forms. The inflammatory response varies considerably from one area of the lungs to another; some areas have well organized granulomas with whorls of epithelioid cells and necrosis, whereas other areas have caseous necrosis. Demonstration of *H. capsulatum* is very difficult with hematoxylin and eosin (H&E) staining and is almost impossible in areas without necrosis. Gridley's stain is useful for demonstration of yeast cells. The periodic acid–Schiff (PAS) stain can be negative despite the presence of silver-staining yeast cells by Gomori's

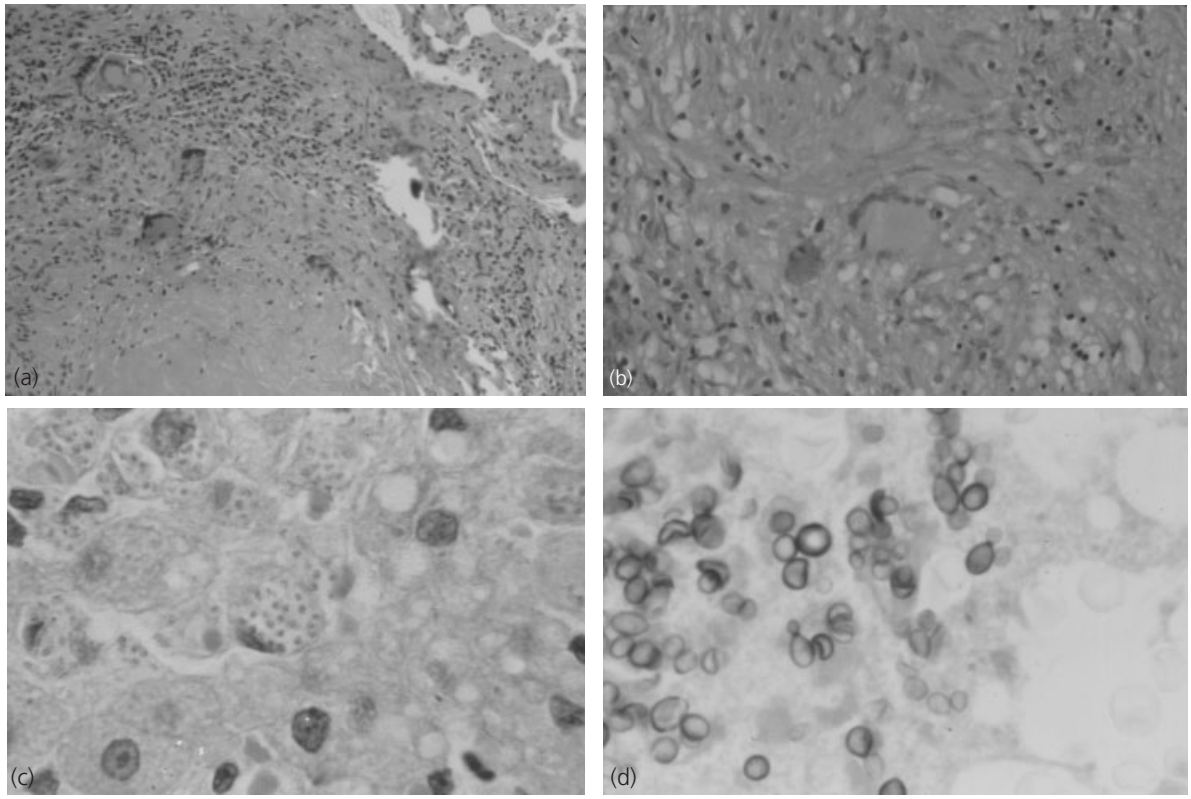

Figure 12 *Histopathology of histoplasmosis capsulati.* **(a)** *Cross-section of the lung from a patient with histoplasmosis showing granulomatous inflammatory response consisting of mononuclear cells and giant cells with a central area of necrosis (H&E stain; magnification ×1 200).* **(b)** *Cross-section of a mediastinal lymph node showing caseous granulomatous lymphadenitis resulting from* H. capsulatum *var.* capsulatum. *Note the epithelioid cells and giant cells around the necrotic centre (H&E stain; magnification ×1 200).* **(c)** *Cross-section of the liver showing numerous intracellular yeast cells in histiocytes with associated mononuclear cell infiltration (H&E stain; magnification ×1 200).* **(d)** *Cross-section of a lung granuloma showing intact and some degraded yeast cells (GMS stain; magnification ×1 200). (Courtesy of Dr Joan Barenfanger, MMC, Springfield, IL)*

methenamine silver (GMS) stain – the preferred technique for recognition of the yeast cells of the three varieties of *H. capsulatum*. The organisms from old lesions may not grow on culture (Figures 13 and 14).

A critical issue in pulmonary pathology is the distinction of infection from non-infectious granulomas in the lung. In Wegener's granulomatosis, necrotizing vasculitis of blood vessels is prominent, even in areas without necrosis of surrounding tissues. Vessel walls are destroyed and infiltrated with acute and chronic inflammatory cells, mixed with multinucleated giant cells and histiocytes. If one considers only the lungs and not the lesions of Wegener's granulomatosis in the upper airway or kidney, the tissue response can be quite similar to that of chronic pulmonary histoplasmosis capsulati. Lymphomatoid granulomatosis differs in that the vessel necrosis is less prominent, cellular infiltrates are present in all layers of the vessels, and the lesions are predominantly angionecrotic. Lesions of sarcoidosis can also be mistaken for those of histoplasmosis capsulati. Within infectious diseases, tuberculosis most closely resembles histoplasmosis, histopathologically. In cryptococcosis, necrotic areas contain large collections of yeasts that can be easily recognized by special stains. Furthermore, cryptococcal granulomas have yeast cells throughout the lesion. *C. immitis* is the fungus with an inflammatory response that mimics that of histoplasmosis, but spherules of *C. immitis* are easy to find and are distinctive. Likewise, *B. dermatitidis* yeast cells have thick, double refractile cell walls with a broad-based septum between the mother and daughter cells, and are usually associated with a mixed suppurative and granulomatous tissue reaction.

Involvement of hilar lymph nodes with necrotizing granulomas and calcification is common in pulmonary histoplasmosis (Figure 12). Patients who progress to fibrosing mediastinitis have increasing effacement of lymph node architecture with caseous necrosis and dense bands of collagen about the node (Goodwin et al. 1972). With progression of the lesion, fibrotic compression of pulmonary veins, superior vena cava, bronchus or pulmonary arteries can occur. Caseous nodes can adhere and rupture into the esophagus or, rarely, the bronchus. In patients with pericarditis, thickened pericardium shows nonspecific inflammation more often than a granulomatous response or *H. capsulatum*

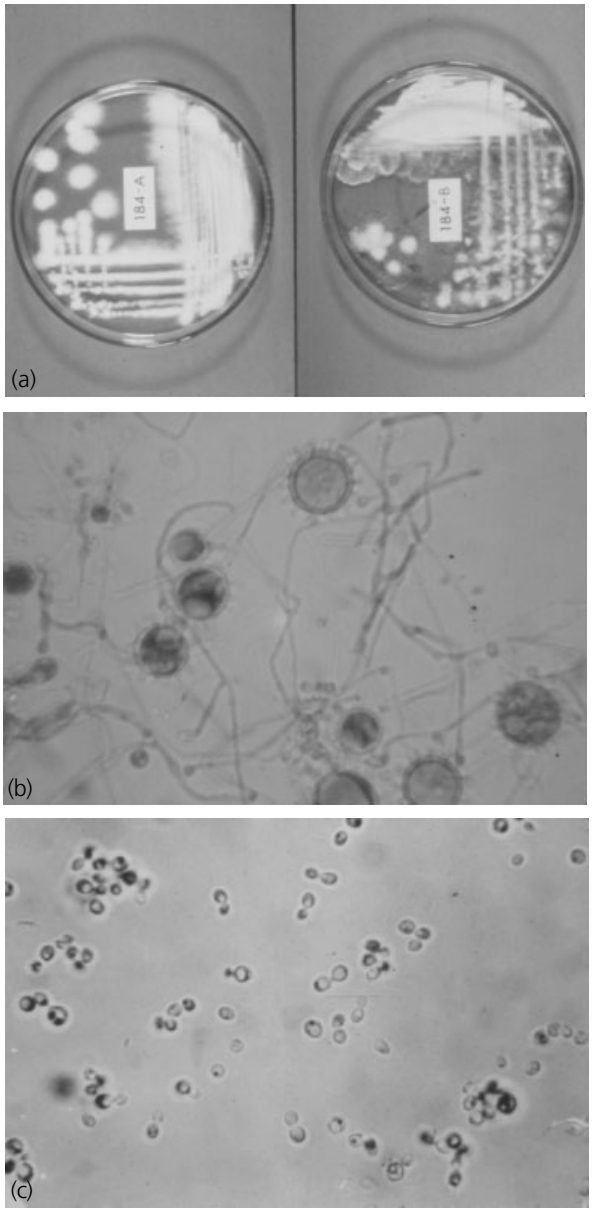

Figure 13 *Morphology of* H. capsulatum *var.* capsulatum. **(a)** *Mycelial colonies of brown (left) and albino (right) types at 25°C after 4 weeks (Cotton blue stain).* **(b)** *Microscopic appearance of* H. capsulatum *in mycelial form showing branching septate hyphae with microconidia (2–4 μm) and tuberculate macroconidia (9–15 μm) (Cotton blue stain; magnification ×3 400.)* **(c)** *Yeast form growth of* H. capsulatum *var.* capsulatum *on brain–heart infusion agar slants at 37°C after 48 hours. yeast cells. Occasionally, caseous subcarinal nodes may be attached to the pericardium.

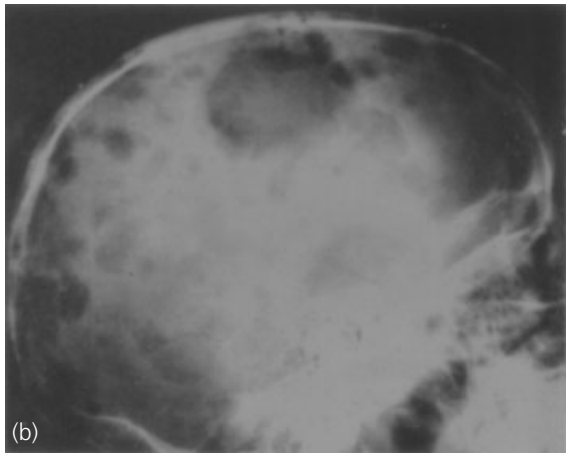
The most prominent lesions of progressive disseminated disease are extrapulmonary. There is a diffuse scattering of infected macrophages throughout the mononuclear phagocytic system (MPS), often referred to as the reticuloendothelial system; granulomas are generally formed poorly, if at all. The organs rich in MPS are most frequently involved. Necrosis is less prominent in lesions outside the lungs because necrosis perhaps reflects an adequate host defense that is compromised in disseminated disease. A notable exception is the adrenal glands where necrosis is a prominent feature. Fungal stains demonstrate a large number of histoplasma yeast cells in lesions with diffuse infiltration by macrophages. In patients with AIDS and other severely immunocompromised hosts, the phagocytic cells are usually engorged with yeast cells, presumably as a result of lack of adequate cytokine production and signaling required for killing of the ingested organisms.

Some extrapulmonary sites have their peculiar lesions. The infected cardiac valves often have large yeast forms or short hyphal cells. The histological characteristics of an embolized vegetation of a peripheral artery can readily be confused with candidal infection. In the CNS, histoplasmosis capsulati may present only as a meningitis or one or more cerebral granulomas. In meningitis, the organisms can be so sparse that histological sections may miss the diagnosis unless cultures of basilar meninges are done.

HISTOPLASMA CAPSULATUM VAR. *DUBOISII* INFECTION

H. capsulatum var. *duboisii* is endemic to the tropical regions of Africa and the island of Madagascar. It was



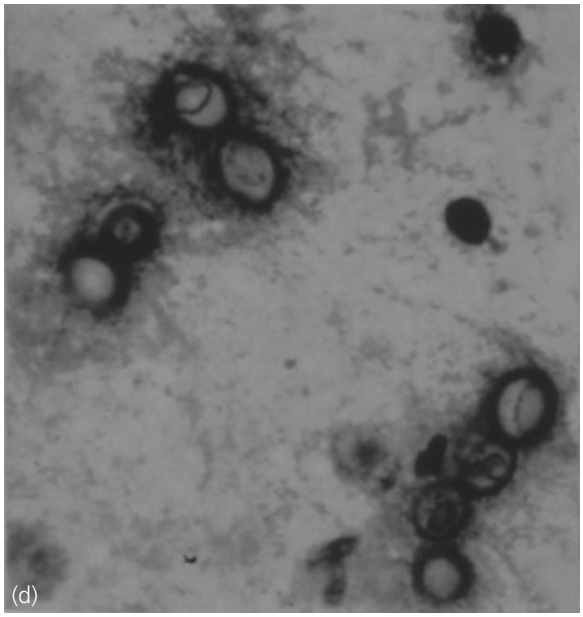


Figure 14 (a) *Head of a male child with disseminated form of histoplasmosis duboisii showing multiple subcutaneous abscesses over the bone defects shown in* **(b)**. **(b)** *x-Ray of the skull with multiple osteolytic defects resulting from granulomas in the diploe which have extended to involve both the inner and outer tables of the vault.* **(c)** *A female patient with two large abscesses on the back caused by* H. capsulatum *var.* duboisii. **(d)** *Yeast cells of* H. capsulatum *var.* duboisii *in pus (PAS stain; magnification ×800). contrasted to *H. capsulatum* var. *capsulatum* by Houston (1994). Cases have also been diagnosed in travelers who have visited those areas and immigrants from central Africa. Several cases have been reported in people with AIDS. Exposure to bat or bird droppings appears to be a risk factor for acquisition of histoplasmosis duboisii. Isolation of the *duboisii* variety from the environment was conclusively established in 1994 by Gugnani et al.

The clinical manifestations of *H. capsulatum* var. *duboisii* infections differ from those seen in patients infected with the *capsulatum* variety of *H. capsulatum*. Although the infection is acquired by inhalation, the most common clinical manifestations in histoplasmosis duboisii involve skin, bone, and subcutaneous tissues (Cockshott and Lucas 1964). Multiple osteolytic lesions are commonly found in rib, vertebra, femur, humerus, tibia, skull, and wrist (Williams et al. 1971). The granulation tissue from a vertebral lesion may cause compression of the spinal cord, resulting in paraplegia. Skin lesions may be papular, nodular, ulcerative, circinate, and eczematoid. Formation of subcutaneous abscesses from underlying bone lesions are common in histoplasmosis duboisii. With the enlargement of nodular or papular lesions, the centre ulcerates. Patients with only skin or bone lesions may have an indolent disease course, and may sometimes recover without any treatment.

If present, the pulmonary lesions of histoplasmosis duboisii, in chest radiographs, may have a diffuse

reticular pattern extending throughout both lung fields or localized with or without involvement of mediastinal lymph nodes. These radiographic findings are similar to that observed in *H. capsulatum* var. *capsulatum* infections. The patients with a mild form of the disease presumably recover without any treatment.

In patients with the disseminated form of histoplasmosis duboisii, multiple lesions are usually present in the liver, spleen, lymph nodes, bone marrow, and other visceral organs. Fever, anemia, and loss of weight are common accompaniments. Such patients follow a progressive, wasting course and their disease may prove fatal if untreated. At autopsy, numerous nodular lesions are found throughout the reticuloendothelial system. This feature is remarkably similar to that observed in patients with histoplasmosis capsulati (Wheat et al. 1981).

Microscopic examinations of tissue sections show numerous organisms in areas of granulomatous inflammation (Williams et al. 1971). The giant cells contain large, thick-walled yeast cells that are larger than those of the *capsulatum* variety. An acute inflammatory response may be seen in ulcerated skin lesions and in soft tissue abscesses. The well-organized granulomata with their caseous centres and surrounding epitheloid cells, which are commonly associated with pulmonary histoplasmosis capsulati, are rarely observed in histoplasmosis duboisii.

Diagnosis is made by fungal stains that reveal ovoid, thick-walled yeasts measuring 12–15 μm in diameter that are distinct from those of *H. capsulatum* var. *capsulatum* (2–5 μm in diameter). Morphologically, *H. capsulatum* var. *duboisii* and var. *capsulatum* are identical in culture; however, they can be distinguished by differences in the size of their yeast-form cells in experimentally infected animals. Treatment of histoplasmosis duboisii is similar to that of *H. capsulatum* var. *capsulatum* infections. Both amphotericin B and itraconazole are effective (Eichmann and Schar 1996) in HIV-positive as well as in HIV-negative individuals (Figure 14).

HISTOPLASMA CAPSULATUM VAR. *FARCIMINOSUM*

As has been emphasized, histoplasmosis farciminosi is an equine disease. Clinically, it is a virulent disease notable for the suppuration of the superficial and subcutaneous lymphatic vessels, especially in the neck and limbs of the infected animals. Other parts of the body are more rarely involved – flanks, back. In general, the initial lesions are most frequently associated with those parts of the body which are most apt to be subject to wounds by kicks, contusions, and harness galls. The ulcerations are painful and usually pruritic. The infected lymphatic vessels become dilated and form a linear series of abscesses which in time rupture and discharge serosanguineous pus for several weeks. Noncutaneous lesions may occur in the mucous membranes and proliferate along the nasal septum to the pharynx, larynx, and trachea. Ocular involvement may also occur, especially on males. Such infections are characterized by watery discharge from one or both eyes with blepharitis that may lead to the closing of the affected eyes (Singh 1966). Dissemination of histoplasmosis farciminosi is essentially through the lymphatic ducts. Involvement of the internal organs has not been documented.

Diagnosis is based on the detection of the tissue-form cells of the dimorphic *H. capsulatum* var. *farciminosi*. These unicellular hyaline cells are 2.5–3.5×2.0–3.0 μm. They are best detected in pus smears on tissue sections through staining with the combined GMS–H&E stain or the PAS stain. The yeast-like cells are found to be intracellular within phagocytes. As noted previously, they are indistinguishable from the tissue-form cells of the *capsulatum* variety of *Histoplasma* in respect of size, form, and staining reactions. Confirmation of isolating the etiologic agent can be achieved by the use of a soil extract medium as reported by Weeks et al. (1985) and by converting the mycelial form to its yeast-like form by growing the isolates at 37°C in brain–heart infusion agar with or without 5 percent sheep blood.

Treatment is empirical as no consistent effective treatment has been developed. Surgery for extirpation of early lesions has been effective in some instances. Recently administration of amphotericin B has been recommended (Chermette and Bussieras 1993). For further information on histoplasmosis farciminosi, the readers are referred to the 1980 publication of Chandler, Kaplan, and Ajello.

Paracoccidioidomycosis

GIL BENARD AND MARCELLO FRANCO

Etiologic agent	1	Laboratory diagnosis	12
Host responses	5	References	15

ETIOLOGIC AGENT

History

Paracoccidioidomycosis, a term officially recognized in 1971 in Medellín, Colombia, during a meeting of mycologists, is a deep mycosis which may be manifested as an overt disease or occur as an asymptomatic form. The mycosis is of great interest for Latin American countries and is caused by a dimorphic fungus *Paracoccidioides brasiliensis*, which still has not revealed its perfect, sexual phase (Lacaz 1994a).

In 1908, in the city of São Paulo, Brazil, Adolpho Lutz (1855–1940), one of the greatest scientists in Brazilian medicine, described this morbid entity for the first time in two patients, who presented with extensive oropharyngeal lesions associated with cervical lymphadenitis. Lutz was able to isolate the microorganism in culture; the parasite's colony showed gross resemblance to the fur of a white rat, grew as a filamentous microorganism in various media at room temperature, and had a dimorphic nature. As Lutz never saw endogenous sporulation, he considered the fungus to be different from *Coccidioides immitis*, a fungal agent previously described in Argentina (Lutz 1908).

Between 1909 and 1912, Alfonso Splendore (1871–1953), a distinguished Italian bacteriologist, observed new cases of the disease, gave a more complete description of its causative agent and of the clinico-histopathological features of the disease, and assigned the causative agent to the *Zymonema* genus under the name *Zymonema brasiliense* (Splendore 1912).

Later on, the disease was baptized 'Brazilian blastomycosis' and soon after, 'South American blastomycosis' due to the observation of cases in other South American countries.

In 1923, Floriano Paulo de Almeida (1898–1977), a researcher working at the University of São Paulo Medical School, confirmed that the agent differed from that of coccidioidomycosis, and, in 1930, after a series of systematic studies, established a new genus within the kingdon of fungi, i.e. *Paracoccidioides*. He revalidated the name of the species created by Splendore and officially assigned the name of the new fungus, *Paracoccidioides brasiliensis*, according to the rule established by Linneus (Campos and Almeida 1927).

Synonymy of the disease then proliferated, with the coining of terms such as paracoccidioidic granuloma, paracoccidioidic granulomatosis, malignant ganglionic granuloma of blastomycetic origin, neotropical blastomycoid granulomatosis, adenomycosis, Lutz disease, and Lutz–Splendore–Almeida disease.

As a result of its geographical distribution, the mycosis was also designated as South American blastomycosis. After the First Pan-American Symposium on Paracoccidioidomycosis, held in Medellin, Colombia, in 1971, the term paracoccidioidomycosis became well established, and is nowadays the denomination universally accepted (PAHO, 1972).

Mycology

The etiologic agent of paracoccidioidomycosis, *P. brasiliensis*, is a dimorphic fungus only known in its asexual state (anamorph). The dimorphism depends primarily on the temperature.

In its parasitic phase and in culture at 35–37°C, the growth is yeast-like. The fungal elements are rounded

cells up to 5–40 μm in diameter, with a well-defined refringent apparently double wall and reproduction by single or multiple buds, which are connected to the parent cells by a narrow bridge. Sometimes, in the lesions, the parasite presents as small diminute yeast cells, measuring about 3–5 μm (Lacaz 1994b).

The type of reproduction of *P. brasiliensis* is characterized by the formation of chromatin masses in the cytoplasm, which may cross already existing small openings in the cell walls, or newly formed ones, dragging the cytoplasmatic mass and the enveloping membrane (Lacaz 1994b).

The variability in size and number of the daughter cells and their connection to the parent cells are characteristic. The large cells, with multiple exosporulation, which in cross-section resembles a pilot's wheel, are pathognomic.

In culture at room temperature, the growth is mycelial. The colonies do not grow rapidly and start to develop after 20–30 days of incubation: they become velvety and cracked, and may show glabrous, cerebriform, and brownish features. Under the microscope, the colonies show fine, septated, interlaced, mycelial hyaline hyphae, 0.8–2.5 μm in diameter. Round to subspherical, 20–50 μm in diameter, terminal, and intercalary chlamydoconidia may be observed (Lacaz 1994b) (Figure 1).

In the parasitic state of *P. brasiliensis*, the blastoconidium has a blastic development which is characterized by the blowing-out of a conidiogenous cell or of a fertile hypha to form a conidium. The electron microscopy studies suggested that both walls of the conidiogenous cell are used in the formation of the conidial wall, which means that the conidia can be considered as holoblastic. Regarding the order of arrangement and the position of the conidium, the terms used for *P. brasiliensis* will be botryose, asynchronous (Lacaz 1994b).

It should be mentioned that *P. brasiliensis* is a eukaryotic cell or eukaryote, showing a cell wall made up by chitin as visualized by periodic acid–Schiff (PAS). This wall can be well detected by electron microscopy.

The molecular aspects of *P. brasiliensis* dimorphism, diagnosis, epidemiology, taxonomy, and genetics have recently been extensively reviewed (San-Blas et al. 2002).

Molecular tools have been used to discover genes with differential expression according to the fungal phase. It is important to stress that glucose polymers are arranged mainly as α-1,3-glucan in the cell wall of the pathogenic yeast phase (95 percent) of the fungus whereas β-1,3-glucan is the only glucose polymer found in the mycelial cell wall (San-Blas 1979). These features have a remarkable importance in pathogenicity and dimorphism of *P. brasiliensis*.

The synthesis in vitro of β-glucan by β-1,3-glucan synthase requires UDP-glucose as the preferred nucleotide precursor. So far, only one related *P. brasiliensis* gene, *FKSP61*, has been cloned and sequenced (Pereira et al. 2000).

In addition, two other DNA fragments have been shown to correspond to distinct glucan synthase genes, which indicates that genes encoding glucan synthases appear to comprise multigene families.

On the other hand, no α-1,3-glucan synthase gene has been reported in *P. brasiliensis*. This polysaccharide is organized as the outer capsule in the yeast phase of the fungus and replaces almost entirely the β-glucan that comprises the neutral polysaccharide of the vegetative mycelial phase, behaving like a virulence factor.

Chitin represents a major structural component of the cell wall with functions in morphogenesis and virulence. Five chitins synthase genes, representing different classes of enzyme, are active in *P. brasiliensis* (Niño-Vega et al. 2000b).

The best studied proteins and genes related to fungal morphogenesis include the heat shock proteins (Hsp). The Hsp 70 gene isolated in *P. brasiliensis* is differentially expressed during transition from the mycelial to yeast form (Silva et al. 1999).

The synthesis of polyamines is a metabolic process that appears to be involved in the dimorphic process; this process is catalyzed by ornithine decarboxylase (ODC). The *PbrODC* gene has been cloned and sequenced in *P. brasiliensis*.

Several *P. brasiliensis* DNA sequences of potential diagnostic use have been reported, such as a species-specific 110 bp DNA fragment, a species-specific 14-base DNA probe originated from the 28S ribosomal gene of the fungus, a specific 418 bp fragment from the 5.8S rDNA flanking internal transcribed spacer regions, and primers derived from the sequence of the gene coding for the immunodominant gp43 antigen (Goldani et al. 1995; Sandhu et al. 1997; Imai et al. 2000).

The molecular methods used for identifying *P. brasiliensis* are also used for epidemiologic screening and in molecular taxonomic studies. Random amplified polymorphic DNA (RAPD) analysis of *P. brasiliensis* strains have indicated that DNA variation correlates with geographical areas but not with pathological findings (Calcagno et al. 1998). RAPD analysis also achieved discrimination that reflected degree of virulence. Altogether these data suggest that *P. brasiliensis* may consist of several genetically distinct groups under a single morphological species (Molinari-Madlum et al. 1999).

The integration of data between morphological features, virulence, and DNA variation might eventually lead to a more appropriate species differentiation concept in the fungus.

Molecular methods have also been useful to redefine the taxonomy of *P. brasiliensis*. Phylogenetic comparison based on large subunit (28S) ribosomal rDNA sequences has placed the fungus as belonging in the order Onygenales, family *Onygenaceae* (phylum Ascomycota) (Leclerc et al. 1994).

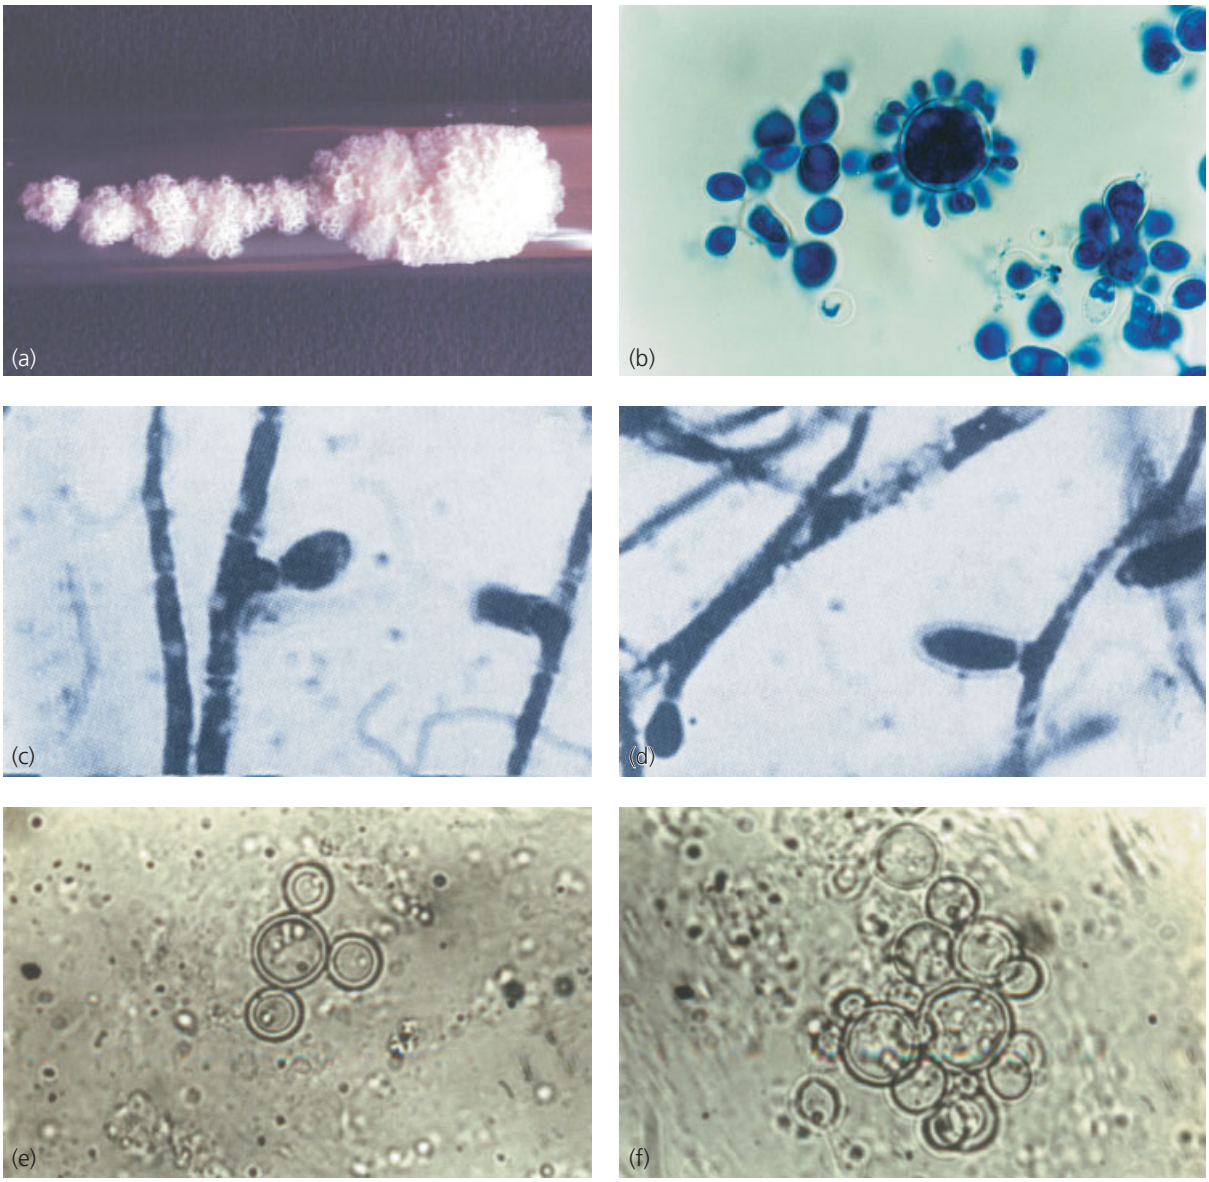

Figure 1 (a) *Macroscopic aspect of a* Paracoccidiodes brasiliensis *culture at 37 C ön Fava Netto's medium.* **(b)** *Yeast-like forms on lactophenol culture grown at 35°C.* **(c, d)** *Mycelial form grown at 25°C on Sabouraud agar, showing fertile hyphae producing terminal conidia.* **(e, f)** *Direct examination: KOH mount of sputum showing yeast-form-like cells.*

Four or five chromosomes of variable molecular weights have been reported in *P. brasiliensis* depending on the samples and the techniques used for karyotyping. The data so far indicate that the fungus has chromosomal polymorphism, due to genetic translocations or large-scale deletions, as is the case for other pathogenic fungi. The phenomenon may play a role in promoting the genetic variability and accelerated evolution of different isolates (Montoya et al. 1999). The genome size of *P. brasiliensis* is around 45.7–60.9 Mbp and the nuclei of the yeast cells may be diploid (Cano et al. 1998).

The *P. brasiliensis* genome project is under way. There has been constructed a *P. brasiliensis* DNA library from the yeast pathogenic forms and sequenced 13 490 Expressed Sequence Tags (EST) and clusters. Sequence analyses of these clusters have already identified several virulence factors (Goldman 2002). In addition, a similar approach is aiming at identifying expressed genes in mycelium and yeast forms. Seven genes that code for members of the Hsp family have been identified which could potentially be involved in the dimorphic and thermoregulated transition of the fungus. Genes coding to multidrug resistance proteins have also been identified. These issues will only be further addressed as gene-disruption and/or RNA interference approaches become available for the pathogen (Felipe et al. 2002).

Ecology and epidemiology

TRANSMISSION AND ECOLOGICAL NICHE

Paracoccidioidomycosis is acquired most commonly by inhalation of propagules from the filamentous phase of the infecting agent present in the nature (Borelli 1963–64). The true prevalence and incidence of paracoccidioidomycosis are not precisely known. Many factors contribute to this situation. The mycosis is not a notifiable disease in the countries where it is endemic. Cases are sporadic; neither epidemic outbreaks nor interhuman transmission have been reported to date. Familiar incidence is rare. Moreover, the ecological niche of the fungus is not yet solved (Restrepo et al. 2001). The long time of incubation, sometimes decades, in the most common form of the disease, the chronic form, makes the delimitation of the areas where the disease was probably acquired difficult. Acute/subacute form cases, more rarely seen, make this task somewhat easier. The presence of a significant percentage of children under 14 years of age with the acute/subacute form within a circumscribed region would imply that it is an endemic region, because such children have less frequently moved away from their living place as compared to adult patients The regions considered endemic in Latin America are despicted in Figure 1.

In the face of these difficulties, Borelli (1963–64) created the concept of 'reservárea' for the place in endemic areas where man acquires the infection, and consequently where the fungus has its habitat, in opposition to 'endemic area,' which refers to the place where the disease is diagnosed.

Previous estimates of incidence were based on the number of cases per year diagnosed in traditional mycoses services and encompassed mostly the period from 1940 to 1980. Based on these data, Londero and Ramos (1990) had estimated an annual incidence of one to three cases per 100 000 habitants in highly endemic areas, while Franco et al. (1989) estimated an annual incidence of four new cases per million habitants. However, this may not hold valid because of the increasing urbanization of the population in the Latin American countries in the last decades. A recent study analyzed 3 181 deaths from paracoccicioidomycosis in Brazil, based on 16 years of sequential data. The mean annual mortality rate was 1.45 per million inhabitants, representing the eighth most common cause of death from predominantly chronic or recurrent infectious and parasitic diseases; the data justified classifying the systemic mycosis as a major health problem in Brazil (Coutinho et al. 2002).

The *P. brasiliensis* habitat still is a puzzle and has been reviewed recently (Restrepo et al. 2001). It is presumed that the fungus lives in its saprophytic filamentous phase in humid, protein-rich soils, in areas with small temperature variations, where it would produce the arthroconidia and aleurionoconidia. Once man disturbs this habitat, these small infectious propagules, which are less than 5 μm in diameter, would disperse in the air, be inhaled, and reach the terminal bronchi and alveoli. Thus the strong link that exists between agricultural activity and paracoccidioidomycosis infection and disease. Recently, the role played by deforestation in increasing both exposure and incidence rates has been documented in Brazil in Amerindians and in children (Coimbra et al. 1994; Rios-Gonçalves et al. 1998; Fonseca et al. 1999). Unexpectedly, however, there is only a small number of successful recoveries of *P. brasiliensis* from the soil (Franco et al. 2000). One possible reason comes from a recent study on the action of agricultural pesticides on *P. brasiliensis*, showing that its in vitro growth was inhibited by concentrations of pesticides that can usually be found in agricultural soils (Ono et al. 2001).

Borelli (1963–64) has also previously suggested that the fungus survives in cavities in the underground, associated with rodents' holes and armadillo's burrows. Although there is still no information regarding rodents, the hypothesis is consistent with the recent findings of fungal isolation from the nine bands armadillos (*Dasypus novemcinctus*) (Naiff et al. 1986; Cadavid and Restrepo 1993; Bagagli et al. 1998; Silva-Vergara and Martinez 1999). Moreover, skin surveys of domesticated animals such as cows, horses, and sheep revealed a high proportion of positive responses to paracoccidioidin (Costa and Fava Netto 1978). Serological studies in dogs showed high percentages of positive tests, mainly in dogs from rural areas as compared to urban animals (Mós and Fava Netto 1974; Ono et al. 2001). Up to very recently, the enigma of why *P. brasiliensis* could not be found in autopsies of dogs highly exposed to the fungus as demonstrated by high titers of specific antibodies was explained in principle by the assumption that dogs are extremely resistant to paracoccidioidomycosis, as opposed to coccidioidomycosis. However, a recently proven case of paracoccidioidomycosis in a dog will reshape this discussion (Ricci et al. 2002).

A careful study in Colombia by Restrepo's group attempted to characterize the ecological factors that prevail in the 'reservárea.' Altitude from 1 000 to 1 499 meters above sea level, rainfall from 2 000 to 2 999 mm, presence of humid forests and of coffee and tobacco crops were significantly associated with the disease (Calle et al. 2001). In Brazil more than 800 cases have been notified in the last 6 years in an area at the border of the amazonic region that had experienced an intense migration process and had become a new agricultural frontier (Lima and Durlacher 2003).

AGE AND GENDER

The disease predominates in men aged 30–50 years. It decreases gradually over 60 and abruptly in the young.

This is because the chronic form of the disease is the most frequent presentation of the mycosis, the acute/subacute form representing usually less than 10 percent of the cases. Males are afflicted with much greater frequency than females, with a ratio 14:1 or more, depending on the patient series. The reason for the lower incidence in women was elegantly explained by observations showing that *P. brasiliensis* mycelia and conidia possess an estrogen receptor and that estrogens inhibit the mycelia/conidia to yeast transformation (Restrepo et al. 1997; Aristizábal et al. 1998). These data fit well with the finding that the acute/subacute form of the disease affects equally both genders before puberty, but preferentially men after puberty (Silvestre et al. 1997), and with the knowledge that infection is acquired at an early age with no gender differences (Londero et al. 1987). In the review published by Londero et al. (1996), which included children up to 14 years of age, there was a slight predominance of males in the older group. In endemic areas, skin test surveys showed that positive reactions start before completion of the first decade of life, reaching their peak by 15–19 years of age, and only decrease after the age of 50, probably due to immunological senescence. However, paracoccidioidomycosis disease has occasionally been seen in fertile adult women; in these cases a search for immunosuppressive-associated conditions must be undertaken, with some reports of a disseminated disease in pregnant women (Martinez et al. 1993).

OCCUPATION AND RACE

Almost half of the reported cases in adults occur in individuals whose occupations require extensive exposure to the soil. Among the agricultural activities, work in coffee plantations has been traditionally linked to the mycosis (Naiff et al. 1988; Coimbra et al. 1994). In a recently published epidemiologic survey of 584 cases from an endemic region in São Paulo State, Brazil, bricklaying and masonry were, after agricultural activities, the second most important risk factors, which suggests that digging and excavating may also favor the encounter with fungus from under the ground, as first pointed out by Borelli in 1972 (Blotta et al. 1999). No ethnicity susceptibility has been documented. Although a few studies had previously suggested some link between HLA and disease susceptibility, the influence of genetic traits on the mycosis has thus far not been elucidated (Dias et al. 2000).

GEOGRAPHICAL DISTRIBUTION

The mycosis was limited to continental Latin America until 1987, when cases were reported in the Caribbean islands of Trinidad, Grenada, and Guadeloupe (Restrepo-Moreno 1994). Paracoccidioidomycosis is distributed heterogeneously in the endemic region; areas of high endemicity may be localized next to areas of very low incidence. The highest numbers of cases have been reported from Brazil, Colombia, and Venezuela (Restrepo 1985); 7 000 of the approximately 10 000 patients reported from that period were natives of Brazil (Figure 2). Cases diagnosed outside Latin America referred to individuals who, with no exception, once visited or lived in endemic areas from Latin America up to 10–40 years before (Ajello and Polonelli 1985). Within endemic areas, 10–50 percent of healthy adult individuals react to paracoccidioidin, suggesting previous exposure to *P. brasiliensis*. Caution in the interpretation of these skin test surveys comes from studies showing that concomitant histoplasmin reactivity significantly increases the rate of paracoccidioidin reactivity when crude paracoccidioidal antigens are used. The use of the specific gp43 antigen has significantly reduced the percentage of skin-reactive persons in areas where *Histoplasma capsulatum* is endemic (Kalmar et al. 2004). Recent molecular biology studies have indicated that there are at least five different groups of *P. brasiliensis* strains and that they correspond closely with the borders of the various endemic areas and countries (Niño-Vega et al. 2000a).

OTHER FACTORS

Alcoholism was shown to be a predisposing factor to paracoccidioidomycosis. It also probably accounts for a worse prognosis for this infection, at least because of the poorer compliance to treatment of such patients (Martinez and Moya 1992). Undernourishment is another factor commonly associated with paracoccidioidomycosis (Restrepo and Benard 2004).

HOST RESPONSES

Most authors consider that the infection takes place through the inhalation of fungal propagules and that the lungs are the primary focus of the lesions. In most cases, the initial pulmonary infection does not cause noticeable symptoms. Once the conidia reach the terminal bronchi or alveolar spaces, the conidia to yeast transformation takes place (McEwen et al. 1987). In some cases, the fungus disseminates by the lymphohematogenous route, producing distant subclinical and quiescent foci. Apparently, the local defenses are capable of controlling fungal spread, but some viable yeast cells may remain silent in such foci in the pulmonary/mediastinal lymph nodes or even elsewhere. Rarely, the initial pulmonary infection overcomes the host's immune defenses, causing an acute/subacute disease, the juvenile type, with predominant involvement of the reticuloendothelial system. Most often, the quiescent foci remain so throughout life, as demonstrated by the high number of subclinical infections versus the low disease incidence of this mycosis in endemic regions (Wanke and Londero 1994). Nevertheless, the most common clinical presentation of the disease is the chronic form, or adult-type disease,

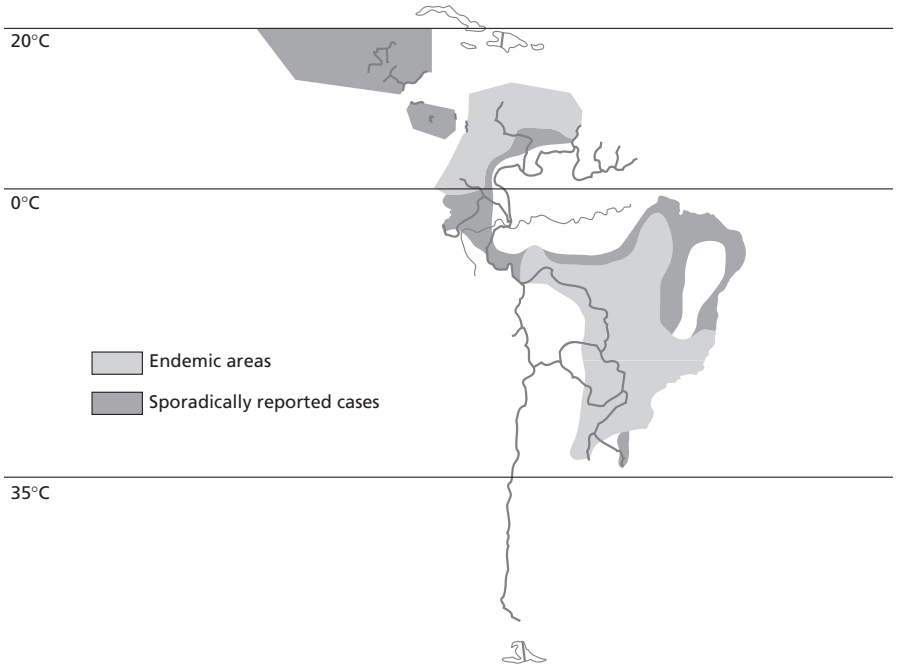

Figure 2 *Geographical distribution of paracoccidioidomycosis.*

believed to result from fungal reactivation in these foci, which not infrequently occurs when the patient has already left the endemic area, as demonstrated by the patients who developed the disease many years after they have migrated to countries outside Latin America (Figure 3).

Actually, paracoccidioidomycosis, either in the acute/subacute or chronic form, is more frequently a disseminated disease, even though clinical manifestations appear to be restricted to a sole organ (Yamaga et al. 2003). However, determination of the degree of dissemination is certainly influenced by the availability of diagnostic procedures. Thus, as a polymorphic disorder that frequently involves more than one organ system, any topographic classification is ineffective. The currently accepted classification of the mycosis takes into consideration not only the organs involved but also the host's immune condition and the disease's

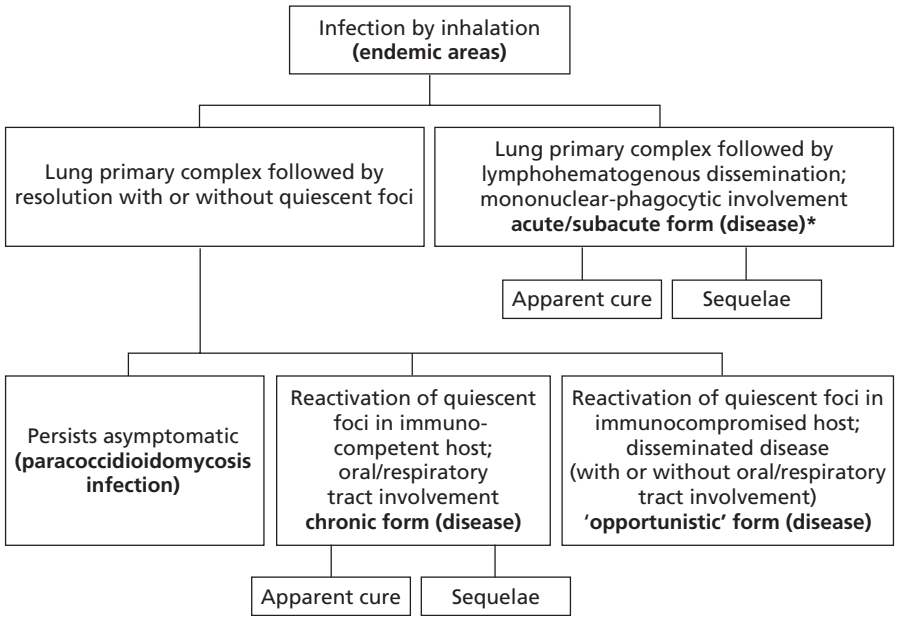

Figure 3 *Classification of paracoccidioidomycosis.*

natural history (Franco et al. 1987). The different outcomes that may result from the *P. brasiliensis*–host interaction are shown in Figure 1. Those individuals who remain infected are categorized as having only the subclinical form. The disease that develops soon after the initial infection is classified as the acute/subacute form. The acute/subacute pattern predominates in children and young adults. According to the severity of the process, acute/subacute patients are assigned to two subgroups, severe and moderate. The chronic progressive form of paracoccidioidomycosis, more common in adult men over 30 years of age, may remain localized in the lungs, the unifocal disease, or may disseminate from its primary foci, the multifocal disease. The chronic form can be mild, moderate, or severe (Franco et al. 1987).

Clinical forms

PARACOCCIDIOIDOMYCOSIS INFECTION

P. brasiliensis-infected persons would correspond to up to 10 percent of the population in countries where paracoccidioidomycosis is endemic, according to previous skin-test surveys (Wanke and Londero 1994). However, there are only sparse reports on the encounter of the fungus in quiescent foci, usually calcified lymph nodes, accidentally or in autopsies of individuals from these countries who died of unrelated causes (reviewed in Restrepo 2000). There are also anedoctal case reports of a pulmonary regressive form (Restrepo et al. 1976; Londero 1986). The study of the morphology and viability of the dormant yeast cells from a patient's residual lesion demonstrated a large proportion of aberrant cells, but there were still 5 percent viable cells (Restrepo 2000). Analysis of some immunological parameters from a small number of infected individuals revealed a Th1-type immune profile that distinguishes them from patients with this disease or cured individuals (Mamoni et al. 2002). Another example is a recent serological survey of blood donors from the countryside of a Brazilian endemic region, employing a more sensitive test, which disclosed that 12 percent of the putatively healthy donors produce specific antibodies (Botteon et al. 2002). The reasons why in some of these infected persons the fungus reactivates at some moment and provokes the chronic form of the disease are not known. A thorough clinical and immunopathological study of persons living in endemic areas is still lacking and is needed before any definitive statement on the concept of paracoccidioidomycosis infection can stand.

ACUTE/SUBACUTE FORM OF THE DISEASE

The time elapsed from infection to the onset of symptoms in the acute/subacute form is not precisely known, but has been estimated to be short, a few months. The acute form involves preferentially the reticuloendothelial system. Fever, malaise, weight loss, and emaciation may be seen in the acute/subacute form. Actually, only a minor proportion of the cases reported have had lung symptomatology. However, this involvement may be underestimated because the severe extrapulmonary lesions tend to minimize the more discrete respiratory manifestations (Londero 1986). Frequently, the mycosis is misdiagnosed as ganglionar tuberculosis or certain lymphomatous disorders. However, induced sputum or other maneuvers may reveal the characteristic *P. brasiliensis* yeast cells (Restrepo et al. 1989). New imaging methods, such as gallium and computerized tomography, have allowed detection of incipient or discrete interstitial pulmonary lesions not revealed by plain radiographs (Funari et al. 1999; Yamaga et al. 2003).

Mucosal lesions are rather exceptional, but skin involvement is more common and tends to be multiple, in contrast with the chronic form (Restrepo and Benard 2004). The lesions represent hematogenous spread of the fungus. In this case, they may appear as ulcerated or ulcerovegetative lesions, papules, crust-covered ulcers, usually at the same stage of development. Sporadic reports of septic shock due to septicemia by *P. brasiliensis* show that the fungus can be bloodborne.

Almost every patient with acute/subacute paracoccidioidomycosis exhibits involvement of the superficial and/or deep lymph node chains. Lymph nodes vary in size, number, consistency, and location; with time, they liquefy, forming abscesses or fistulae (Figure 4).
The spleen and liver are frequently involved. Splenic lesions are nodular or miliary. Gross hepatic lesions may not be apparent, but histopathological examination regularly reveals fungal invasion of this organ (Teixeira et al. 1978). Abdominal lymph node involvement is also common. Hypertrophied lymph nodes, usually generalized but particularly periaortic, around the hepatic hilum and in the retroperitoneum, can be detected by radiological examination. Patients may complain of abdominal masses, lymph node enlargement, diarrhea, vomiting, abdominal distension and/or pain, and ascites. Coalescent masses may become palpable and may result in extrinsic compression of adjacent structures, leading to jaundice (by compression of the biliary duct), pancreatitis, or intestinal obstruction (Martinez et al. 1979a).

The intestinal mucosa may be affected and the involvement may be secondary to blockade of the regional lymphatic flow, with retrograde progression of *P. brasiliensis* to the mucosa, a process resulting in mycotic enteritis (Martinez et al. 1979b). In this case, the submucosal inflammatory process is granulomatous, fungal cells are visualized, and the intestinal changes may vary from dilated loops, edema, congestion, nodule formation to multiple mucosal ulcers (Martinez et al. 1979a).

Figure 4 *Subacute form of paracoccidioidomycosis in:* **(a)** *a young adult man: enlarged cervical suppurated lymph nodes;* **(b)** *a girl: suppurated axilar lymph node.*

Recent studies have also shown bone marrow infiltration mainly, but not exclusively, in the acute/subacute form of the disease (Resende 2000). The histological pattern is variable but appropriate staining always displays fungal cells. Bone marrow invasion is frequently associated with marked eosinophilia (Shikanai-Yasuda et al. 1992a). Bone and joint lesions are frequent, and appear closely related to bone marrow infiltration. The lytic lesions mainly locate at the diaphyseal or metaphyseal–epiphyseal regions of the long bones, but ribs, skull, phalanges, and vertebral lytic lesions have also been documented. A pathological fracture may occasionally occur.

CHRONIC FORM

Most often, chronic-form patients present a history of a few to several months of cough, either productive or not, weight loss, anorexia. Fever may be absent or present in low grade and nocturnal, as in tuberculosis, which is the main differential diagnosis. Occasionally, these respiratory symptoms are mild and the patient seeks medical care only when lymphohematogenous dissemination results in lymph node involvement or distant cutaneous lesions. Plain films taken during admission reveal the primary, pulmonary focus. The pulmonary involvement may be present as micronodular or miliary, nodular, infiltrative or interstitial, cavitary, fibrotic, or mixed patterns (Valle et al. 1992) (Figure 5). Emphysematous areas, pleural thickening, and enlarged hilar and mediastinal lymph nodes can also be observed. Right ventricular hypertrophy may be found in cases of long duration. Lung involvement is probably secondary to a chronic lymphangitic process due to the fungus itself and to the host's response represented by formation of granulomas and fibrosis, the latter predominating at the perihilar region (Tuder et al. 1985). This aspect correlates with the butterfly-like (peri-hilar) micronodular and interstitial infiltration observed on plain films.

Alternatively, in some patients the main complaints may be dysphagia and hoarseness. Generally they are associated with lung infiltrates on the x-ray, and in these cases the decrease in the nutritional status is more prominent due to the patient's impairment in swallowing. The lesions in the oropharyngeal and laryngeal mucosa may be infiltrative, ulcerated, nodular, or vegetative, and usually have a granulomatous aspect (Sant'Anna et al. 1999) (Figure 6). The base of the ulcerated lesions is usually covered by small abscesses

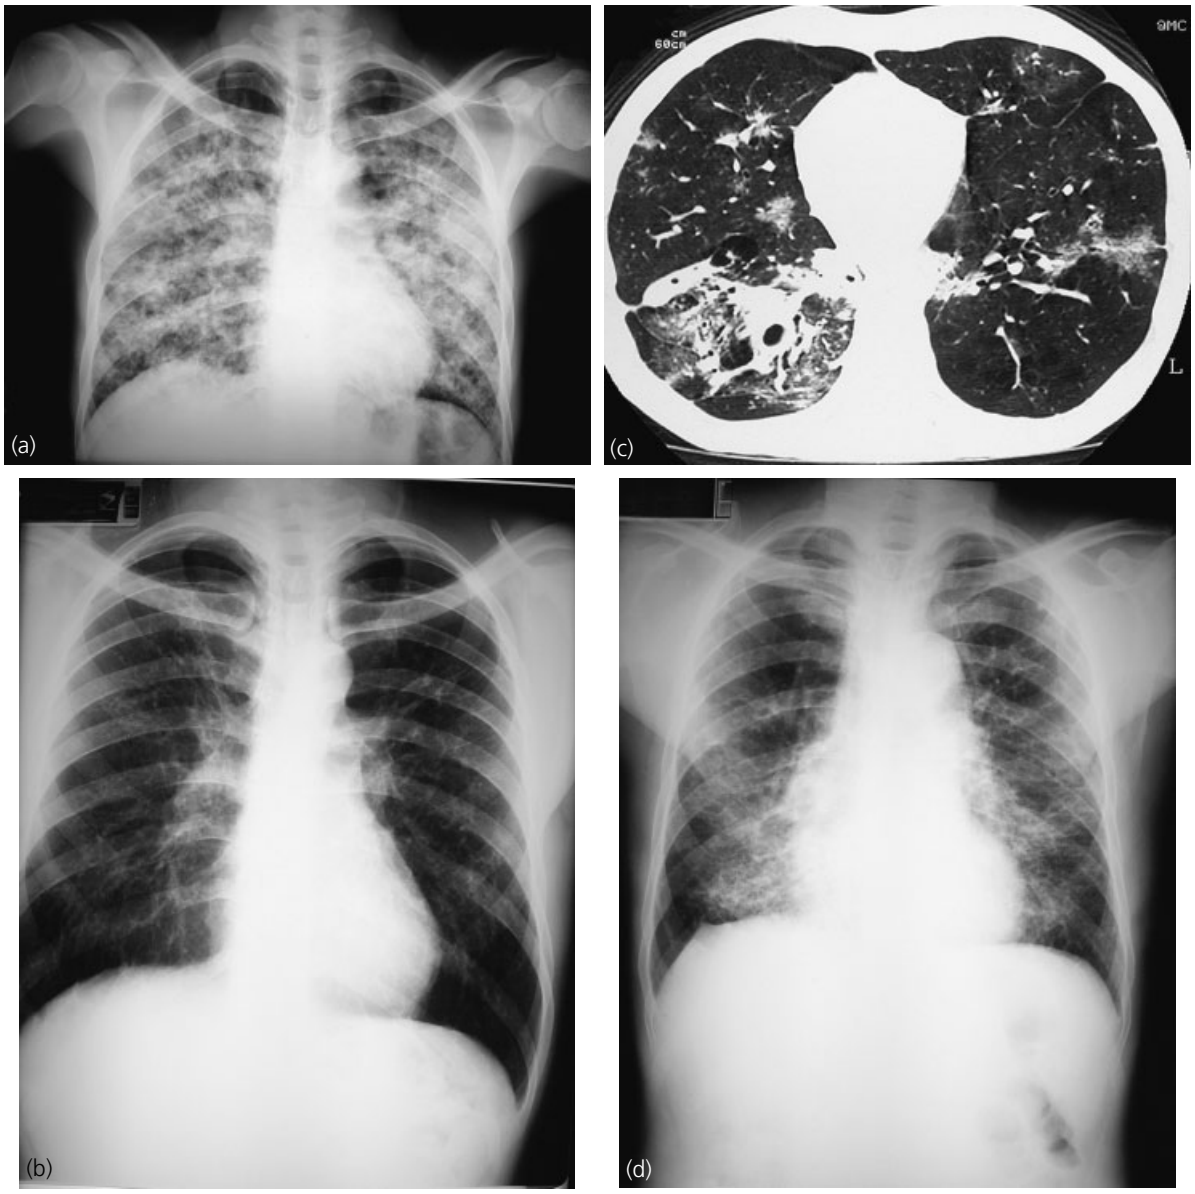

Figure 5 *Pulmonary involvement in the chronic form paracoccidioidomycosis:* **(a)** *extensive pneumonic involvement of the lungs and* **(b)** *the same patient, after 2 years of treatment, with discrete fibrotic, mainly perihilar, lines;* **(c)** *computed tomography showing diffuse pleuropathy with bronchocentric nodules, ground-grass opacities, cavities of several sizes, airspace consolidations, and centrilobular opacities (<1 mm) associated with bronchiectasis and parenchymal distortion.* **(d)** *Micronodular and reticular bilateral infiltrates predominating in the middle and lower fields.*

(the mulberry-like lesions) that probably represent fungal dissemination through the lymphatic system, as they are usually accompanied by regional lymph node involvement (Castro et al. 1999a). Cutaneous lesions are mostly represented by contiguous involvement of the perioriﬁcial mucosal lesions or draining lymph nodes or may represent hematogenous spread in patients with long-lasting disease. The latter, thus, have no preferential localization. The adrenals are often involved in patients with the chronic form of the mycosis, but only a small proportion of them will suffer from adrenal hypofunction or insufficiency (Addison's disease) (Del Negro et al. 1980). The glands containing multiple, granulomatous foci, and diffuse necrosis may be seen in the most severe cases. Recently, silent CNS granulomatous-like lesions attributable to paracoccidioidomycosis have been reported in a small survey of patients using magnetic resonance imaging; the clinical importance of this finding awaits confirmation (Castro et al. 1999b). On the other hand, granulomatous involvement of the spinal cord has been reported in a sizable number of patients and is a severe condition because it is frequently associated with significant, often irreversible, neurological impairment.

'OPPORTUNISTIC' FORM

Paracoccidioidomycosis, as an apparently opportunistic infection in a patient with cancer, was first documented by Lacaz et al. in 1948. The association with hematological malignancies, predominantly, or other types of cancer, generally resulted in a disseminated form of the mycosis with clinical features of both the acute/subacute and chronic forms (Marques and Shikanai-Yasuda 1994). Unless the clinician is armed with a high degree of suspicion, the diagnosis of the mycosis is delayed. The same applies to AIDS patients. This subject has been recently reviewed (Benard and Duarte 2000). It is believed that in most instances it represents reactivation from quiescent foci as a result of the failure of the immune surveillance in blocking the parasite multiplication. The two reasons for the lower than expected number of cases of this mycosis in patients with the acquired immunodeficiency syndrome (AIDS) are supposedly that the two infections have non-overlapping epidemiologic features (e.g. urban versus rural) and that many patients infected with the human immunodeficiency virus (HIV) are on continuous antifungal regimens which, although directed at other fungal infections, also have a suppressive effect on *P. brasiliensis*. Paracoccidioidomycosis mainly afflicts those patients with low (<200 cells/μl) CD4 counts. Nonetheless, it has seldom been the cause of death. As with other fungal opportunistic infections, the mycosis responds adequately to the usual antifungal treatments.

SEQUELAE

Mycologically, successfully treated patients may persist with high morbidity. In the acute/subacute form, disabsorptive syndromes may ensue due to the digestive involvement that resolves by intense fibrosis and obstruction of the abdominal lymphatics, aggravating the nutritional status of the patients, resulting in immunodeficiency and opportunistic infections with high mortality rates (Shikanai-Yasuda et al. 1992b; Benard et al. 1996). Patients may also present with relapsing ascites or chylothorax. In the adult form, fibrosis, either pulmonary, tracheal, labial, or adrenal, leading to, respectively, emphysema, permanent tracheostomy, microstomy, and Addison's disease, are the cause of serious problems in patients who respond to therapy (Mendes et al. 1994). Thus, despite the recent advances in the treatment, these sequelae still preclude the complete recovery in several patients.

Immunology

The initial events of the host–parasite interaction are unknown due to our inability to detect the precise moment when the initial infection occurs. The data collected up to now indicate that the host–parasite interaction in paracoccidioidomycosis is complex, and both arms of the immune system participate in the host's response. On the one hand, the patients have a polyclonal activation of the humoral system with high serum concentrations of specific IgA, IgG isotypes, and IgE (Yarzábal et al. 1980; Biagioni et al. 1984; Baida et al. 1999; Biselli et al. 2001; Mamoni et al. 2002). However a protective role for antibodies has not yet been demonstrated. On the other hand, there is hyporesponsiveness of the patients' T-cell-mediated immunity characterized by decreased lymphocyte proliferation and absence of hypersensitivity skin-test responses, the intensity of which parallels the severity of the disease and correlates inversely with the amount of circulating anti-*P. brasiliensis* antibodies (Musatti et al. 1976; Motta et al. 1985). This imbalance was particularly noted when antigen-specific responses were analyzed (Benard et al. 1996, 1997; Oliveira et al. 2002). Several studies showed that a marked imbalance in the cytokine secretion pattern underlies this picture: lack or strongly decreased secretion of Th1-type cytokines (IL-2, IL-12, and IFN-γ) associated with normal or increased secretion of Th2 cytokines (IL-10, IL-5, and IL-4) (Karhawi et al. 2000; Benard et al. 2001; Oliveira et al. 2002). Previous studies on animal models of paracoccidioidomycosis had already shown that Th2-type responses dominated over Th1-type responses (Kashino et al. 2000). Recently, the role of IL-10 and IL-12 in the regulation of the host's immune responses has been emphasized (Romano et al. 2002). In situ studies of patients' biopsy lesions have shown overexpression of TGF-β, a cytokine with strong immunosuppressive activity (Neworal et al. 2001; Parisi-Fortes et al. 2001). Furthermore, high levels of specific antibodies of the IgE and IgG4 (switch dependent upon IL-4) isotypes were found in patients with the acute/subacute form of the disease as well as in chronic cases with severely disseminated disease, denoting the Th2 control of the humoral immune response in these patients (Biselli et al. 2001; Mamoni et al. 2002). Another aspect in favor of Th2 control was the observation of peripheral and bone marrow eosinophilia in severe cases, an abnormality linked to increased production of IL-5 (Oliveira et al. 2002). Thus, apparently in

the acute/subacute disease, the immune response fails to control the proliferation of the fungus from the beginning of the infectious process due to a profoundly downregulated Th1 response concomitant to upregulated Th2 immune response. In chronic less severe cases, the initial infection is apparently controlled, which allows a better balance of the immune response, with lower antigenic challenge and a less marked Th2 immune response. Apoptosis of the antigen-specific T cells has also been linked to the depressed cell-mediated immune response (Cacere et al. 2002). Patients with apparent cure demonstrate strong lymphocyte proliferative responses as well as positive skin tests, probably in consequence of the recovery of the fungal antigen-induced Th1 type reactivity (Benard et al. 1996; Karhawi et al. 2000).

The cytokine imbalance also affects the macrophages, which represent a crucial cell in the host defense mechanism against *P. brasiliensis*. It has been shown that the intracellular killing of *P. brasiliensis* yeast cells and conidia by this cell occurs only when previous activation has taken place (Gonzalez et al. 2000), which in humans has been shown to be mediated by the synergistic action of TNF-α and IFN-γ (Anjos et al. 2002). The main fungal antigen, gp43, appears to directly affect macrophage functions (Benard et al. 2001; Popi et al. 2002). Polymorphonuclear neutrophils (PMN) also participate in the immune response to the fungus, but their role is less well understood. PMNs are found in some paracoccidioidal lesions, specially in those representing acute inflammation or microabscesses (Sandoval et al. 1996); in experimental models they appear early in the inflammatory process and may play a role in the control of the initial infection (Burger et al. 1996). PMNs can also be activated by proinflammatory cytokines to have enhanced anti-*P. brasiliensis* activity (Kurita et al. 2000; Rodrigues et al. 2001) .

Treatment

The disease caused by *P. brasiliensis* can be managed successfully with oral antifungal drugs. Many drugs are available, and the list is still increasing. Historically, sulfa drugs were introduced in 1940 (Ribeiro 1940), followed by intravenous amphotericin B, in 1958 (Lacaz and Sampaio 1958). The use of azole derivatives (miconazole, soon discarded, ketoconazole, itraconazole, fluconazole, and more recently, voriconazole) was introduced in the 1970s. The treatment is divided into an attack phase and maintenance treatment. Two different drugs can be used for each phase, or the same drug can be used for the two phases but at different dosages (Mendes et al. 1994). Among the reasons for this two-phase prolonged treatment is the chronic progressive nature of the disease and the knowledge that all currently available drugs, albeit with apparently different efficacy, are only fungistatic. In parallel, measures in support of the general condition are required, because cellular immune mechanisms may be affected by malnutrition, concomitant infections, or by the disease process itself, and they are crucial to controlling the fungus dissemination.

Sulfadiazine is used at 60–100 mg/kg daily doses divided in four equal parts to a maximum daily dose of 6 g. Water intake and urine alkalinization (usually by bicarbonated water intake) are recommended to prevent crystalluria and tubular deposits of sulfadiazine. Duration of the attack treatment is dictated by the patient's response, once clinical and serological improvement has been attained; in the chronic form, 2–6 months are required; in acute/subacute cases, the duration of treatment should be longer. Slow-acting sulfa drugs (sulfamethoxypyridazine or sulfadimethoxine), 1 g/day, can be provided as maintenance treatment (Mendes et al. 1994). Sulfadiazine is usually recommended for mild to moderate cases, but our own experience is that it can be used for severely ill acute/subacute cases with good results. It can be used for patients who have been treated initially with amphotericin B. Sulfadiazine has been replaced in many services by trimethoprim-sulfamethoxazole (80 mg of trimethoprim and 400 mg of sulfamethoxazole per tablet, two tablets at 8- or 12-hour intervals) due to its easier posology and availability. This combination has the advantage of permitting alternative parenteral administration whenever necessary. Maintenance treatment in these cases can be achieved by using half the dose of the attack treatment or by using slow-acting sulfas.

Amphotericin B is quite effective, but it should be reserved for severely disseminated cases or in whom gastrointestinal involvement may impair drug absorption. A total dose of 1–2 g is usually required to achieve substantial clinical improvement. There are no sufficient data regarding effectiveness of the new amphotericin B lipid formulations in paracoccidioidomycosis.

As to the imidazole derivatives, patients can be treated with 200–400 mg ketoconazole once daily for periods of 6–12 months and low relapse rates have been documented; however, other studies indicated higher relapses rates and the need for 18 months or more of treatment to achieve good results (Del Negro 1982; Restrepo et al. 1983; Marcondes et al. 1984; Dillon et al. 1985; Marques et al. 1985). These discrepant results may be related to differences in severity of disease among the studies and to problems in drug absorption. Indeed, caution should be urged regarding its absorption, which is dependent on acid gastric pH. Poor absorption has been described with concomitant use of antacids, or when the drug is taken with meals (Mendes et al. 1994). Liver toxicity as well as testosterone synthesis blockade, clinically manifested or not by gynecomastia or sexual impotence, should also be evaluated, especially during prolonged therapy.

With the advent of the new triazole, itraconazole, which was shown to be less toxic and more potent in vitro, ketoconazole tends to be used less. Itraconazole is administered in 100 mg capsules that should be given with a meal; a 100–200 mg regimen for adults, and half dosage for children, daily for 6 months, have been shown to be effective in reducing all active lesions in the large majority (98 percent) of patients, including acute/subacute and chronic forms (Mendes et al. 1994). It is important to remember that both ketoconazole and itraconazole penetrate the brain barrier poorly, thus CNS lesions should be carefully discarded. Instead of amphotericin B, we have used itraconazole, at higher doses (300–400 mg adults, 100–200 mg children) for some severe cases with good results, provided there is no involvement of the digestive tract that could hinder its absorption. Some other authors (Marques 2002; Shikanai-Yasuda et al. 2002a) suggest that patients should be kept on maintenance therapy with slow-acting sulfas after clinical and mycological cure to prevent relapses, while other investigators argue that this is not required (Telles 2002; Tobón et al. 2002). Side effects have been few and include transient elevation of hepatic enzymes (Tobón et al. 1995). A randomized trial with sulfadiazine, ketoconazole, and itraconazole for the treatment of patients with moderate severity disease failed to show higher efficacy of one regimen over the others. However, long-term follow-up was not evaluated (Shikanai-Yasuda et al. 2002b). Experience with fluconazole is far less extensive than with itraconazole, and due to its higher cost is still used less. It may be useful in severely ill patients who must be treated intravenously. There is only one report on the successful use of terbinafine in an adult patient (Ollague et al. 2000).

New perspectives in paracoccidioidomycosis treatment include the new itraconazole formulations (oral solution and intravenous formulations) that will probably further extend its indications. A multicentric prospective trial on voriconazole, 400 mg daily for 6 months, showed encouraging results (F.Q. Telles Filho, M.A. Shikanai-Yasuda and L.Z. Goldani, 2003, unpublished observations). This drug will probably be an excellent option due to its efficacy and low incidence of side effects. Nevertheless, some challenges in the treatment of patients with this mycosis still remain. Neither the clinical and laboratory criteria that allow the transition from the attack to the maintenance treatment phases nor the parameters that could be used to end treatment thus assuring that the patient is definitively cured have been fully standardized. The gradual decrease in the titers of the serological tests currently available is one of the laboratory parameters most frequently used; restoration of some cellular immunity responses, such as reactivity to the paracoccidioidin skin test, is also used. Newer methods, e.g. antigenemia detection and molecular biology approaches, will probably be useful.

LABORATORY DIAGNOSIS

Direct examination

The direct microscopic observation of the characteristic *P. brasiliensis* multiple-budding yeast forms in 10 percent potassium hydroxide preparations of clinical specimens is the most recommended way for diagnosing the mycosis (Lacaz et al. 2002). Usually the sources are sputum, secretion, or scraps/debris from ulcerated skin and mucosal lesions, draining material from suppurating lymph nodes or abscesses, bronchioalveolar fluid, etc. Bronchioalveolar, articular, cerebrospinal fluid or other fluids must be centrifuged before examination. For bone marrow aspirates, Giemsa staining is recommended. When the first examination of the sputum is negative, it can be homogenized with an equal volume of 4 percent sodium hydroxide or *N*-acetyl-L-cysteine and then centrifuged again. Visualization of the multiple-budding yeast cells (pilot's wheel) with the well-defined refringent double wall is mandatory, because the *P. brasiliensis* yeast cells may range from a few microns to 30–40 μm, and when small forms predominate they may be mistaken for *Blastomyces dermatitidis*, capsule-deficient *Cryptococcus neoformans*, *H. capsulatum* yeast cells, endospores, and small *C. immitis* empty spherules or even *Pneumocystis carinii* (Silletti et al. 1996).

More recently, several molecular biology diagnostic tests based on polymerase chain reaction (PCR) are being implemented which will probably open a new field in the rapid and specific diagnosis of paracoccidioidomycosis (Motoyama et al. 2000; Lindsley et al. 2001; Sano et al. 2001). For example, the gene for gp43 from 10 *P. brasiliensis* yeast cells/ml of sputum samples could be amplified, providing sufficient accuracy for the diagnosis of the mycosis (Gomes et al. 2000).

Cultures

Cultures from every patient's specimen should be obtained whenever possible. However, they are far less useful in diagnosis compared to direct examination since other more rapidly growing microorganisms such as bacteria, yeasts (especially *Candida*), and contaminant molds eventually present in the samples inhibit their growth. Isolation should be attempted by the use of modified Sabouraud agar, yeast extract agar plus antibiotics and cycloheximide, brain–heart infusion (BHI) agar plus blood and antibiotics (without cycloheximide), or tryptic soy agar incubated at 37°C and room temperature. Cultures should be observed for up to 4 weeks. As the mycelial form is not characteristic, subcultures in BHI, Fava Netto's agar, or peptone–yeast extract–glucose agar, for up to 14 days at 35–37°C, allow yeast conversion and the definitive diagnosis (Lacaz et al.

2002). In cases of severe disseminated disease, mainly those with the acute/subacute form, blood cultures may become positive (Negroni 1993).

Serology

Patients with paracoccidioidomycosis not only have a polyclonal B-cell activation but also produce high amounts of anti-*P. brasiliensis* antibodies, which are long-lasting and generally correlate with the severity of the disease. Once having started the treatment, serological titers tend to fall, accompanying the clinical improvement. Many serological tests have been developed and extensively studied. They are highly useful for both diagnosis (especially in patients with only deep-seated lesions) and treatment follow-up of patients. Agar gel immunodiffusion (ID), complement fixation (CF), and counterimmunoelectrophoresis (CIE) tests have been employed extensively (Mendes-Giannini et al. 1994). The CF tends to be used less often due to its difficult and time-consuming technique. Also available are indirect immunofluorescence, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and the dot blot immunobinding and Western blotting (Mendes-Giannini et al. 1984, 1992; Taborda and Camargo 1993, 1994; Martins et al. 1997). Some of the newer tests have employed purified antigens, which are well characterized and more specific. The use of these purified antigens has resulted in improvement in the efficiency of the serological tests presently available. However, they are still not easily available for most diagnostic centers. The best characterized and most used is the 43 kDa glycoprotein (Puccia and Travassos 1991). ID, CF, and CIE, which employ crude antigens derived from the yeast phase, can detect $\geqslant$95 percent of active cases. Most authorities recommend the use of two different tests, since none of these low-cost, widely used tests *per se* guarantees more than 90 percent sensitivity when employed alone. ID, for example, is very simple and specific. A conjoint effort of several diagnostic centers assessing the value of this test using a reference crude antigen (Ag7) demonstrated it to be 84.3 percent sensitive and 98.9 percent specific (Camargo 1994). Patients with very localized, benign disease may present negative results with these tests, but when tested with more sensitive techniques, e.g. Western blot or gp43-ELISA, the diagnosis is usually reached. Crossreactivity is a less common problem, but may occur between the patients' sera and *Histoplasma* and *Lacazia loboi* antigens (Puccia and Travassos 1991).

The value of serological tests in the follow-up of patients under treatment has also been addressed by several centers. Serial serological evaluation, usually 3 months apart, together with the clinical, mycological, and radiological surveys, can guide the treatment schedule, and two negative results in two of the serological tests routinely employed is an additional criterion that helps in the difficult decision of therapy discontinuation (Restrepo and Benard 2004). The ID, CF, CIE, ELISA, and Western blot tests were shown to be able to document the decline in antibody levels that parallels the clinical improvement: serum antibodies became undetectable approximately 2 years after cessation of therapy, depending on the clinical form (Fava Netto 1961; Ferreira-da-Cruz et al. 1990; Mendes-Giannini et al. 1994; Bueno et al. 1997; Martins et al. 1997; Del Negro et al. 2000). Thus, in this circumstance, rising antibody levels mean a relapse. Nonetheless, a considerable number of patients maintain, sometimes all life long, the so-called 'healing titers,' i.e. the persistence of low serological titers in the tests. This is more frequent in patients with the acute or chronic multifocal form disease (Del Negro et al. 2000). The debate on the clinical relevance of this phenomenon, whether or not it represents the persistence of residual active lesions, thus eventually predicting future relapses, is inconclusive. Part of this problem has been lately addressed by the search of tests for antigenemia detection. Although not yet completely standardized, preliminary results of antigenemia detection in blood and urine reveal that this is a promising tool (Gómez et al. 1998; Salina et al. 1998). It will also be very helpful in the diagnosis of immunocompromised patients, specially with AIDS, in whom the search of antibody response is not a completely reliable diagnostic tool. Antigenemia follow-up studies would also permit a more precise determination of improvement as antigen load decreases with treatment response.

Histopathology

The histopathological features of paracoccidioidomycosis are similar to those of other systemic mycoses and it is essentially characterized by a granulomatous inflammation (Montenegro and Franco 1994).

It was first asserted by Motta that granulomatous inflammation response is assumed to be the most evolved form of the host tissue reactivity against the invading fungal cells. *P. brasiliensis* granuloma generally centers around one or more fungal cells and is made up of giant cells and epithelioid cells. Polymorphonuclear leukocytes may be observed close to the fungi in the central area; surrounding the epithelioid cells, there is a halo of mononuclear cells and frequently of eosinophils. Fungal antigens tend to be trapped inside epithelioid granulomata. In addition to central suppuration, *P. brasiliensis* granulomata may show central necrosis of the coagulation type.

This type of inflammation represents an immune-specific tissue response of the host in an attempt to destroy, block, and circumscribe the parasite and to prevent its multiplication. Accordingly the two clinicohistopathological forms of the disease are classified as

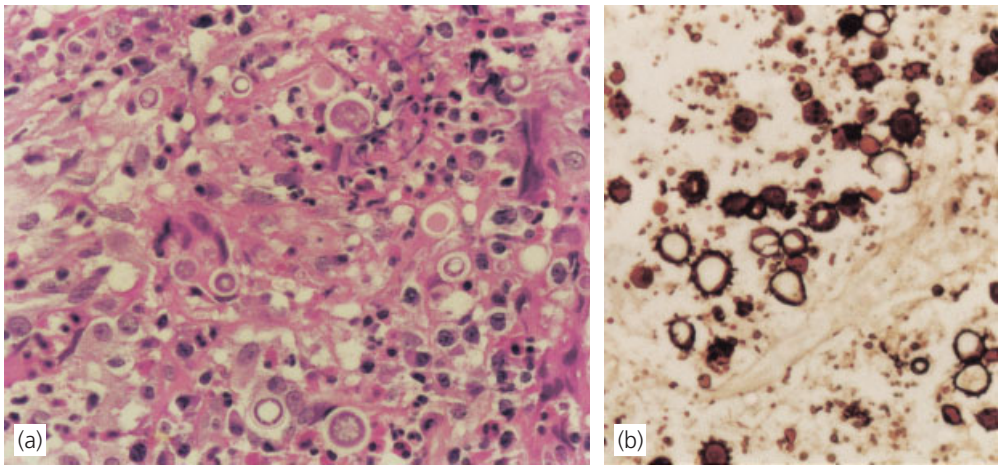

Figure 7 **(a)** *Epithelioid granulomatous inflammation in lymph node with numerous fungal cells in hematoxylin and eosin.* **(b)** *The pathognomic multiple-budding yeast cells are Gomori methenamine silver stain strongly positive.*

the hyperergic and anergic poles. The anergic pole, as seen in cases associated with AIDS, is characterized by disseminated infection, with a mixed suppurative and looser granulomatous inflammation, showing extensive areas of necrosis and large numbers of fungal cells. On the other hand, the hyperergic pole is defined by a more benign, localized infection with persistent cellular immune responses and histopathology showing compact epithelioid granuloma with few fungi (Figures 7 and 8).

Skin and mucous membrane lesions usually exhibit pseudoepitheliomatous hyperplasia and intraepithelial microabscesses. Particularly in ulcerated skin lesions or ruptured lymph nodes, the granulomatous inflammation is associated with a mixed pyogenic component with the formation of intraepidermic microabscesses.

Due to the chronic nature of the infection and the dynamics of the host–parasite relationship, the histopathology of the disease may show areas of extremely active disease characterized by pyogenic reaction and loose granulomata, rich in budding fungal cells, intermingled with areas with compact granulomas, rare fungal cells, and variable degrees of fibrosis. This mixed aspect can be observed either in lymph nodes, skin, or pulmonary lesions, suggesting that the disease evolves through localized new bouts of fungal multiplication and tissue invasion, whereas the adjacent older lesions are on their way to fibrotic resolution. Computer tomographic imaging of the lung confirmed this aspect by depicting areas with alveolar condensation alongside fibrotic and emphysematous zones.

As the morphology of the parasitic forms of *P. brasiliensis* is pathognomonic, the diagnosis of paracoccidioidomycosis is frequently first established by the histopathology examination of a biopsy and further confirmed either by culture or serology. If the parasite is

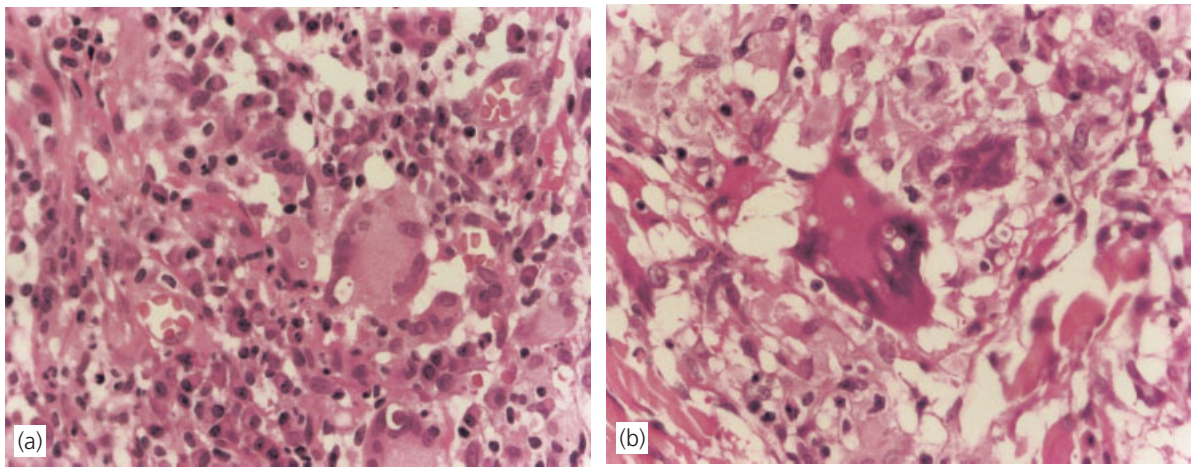

Figure 8 *The two polar histopathological forms of paracoccidioidomycosis:* **(a)** *compact epithelioid granuloma with few fungal cells and* **(b)** *loose, exudative granulomatous inflammation.*

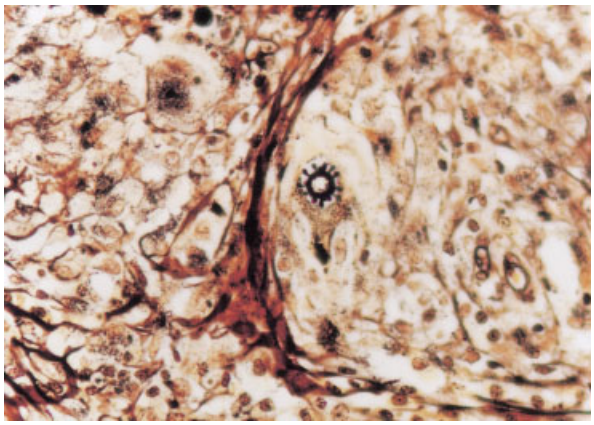

Figure 9 *The pathognomic pilot-wheel yeast form of* P. brasiliensis *in Grocott methenamine silver stain.*

abundant, it may be identified by hematoxylin and eosin stain and confirmed by a special fungal stain such as Grocott silver methenamine (Figure 9). When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Pauciparasitic forms of the *P. brasiliensis* granuloma may occur, which shows a sarcoidic pattern with rare yeast forms. In these cases, the diagnosis may rely on epidemiologic data plus molecular diagnostic tools such as PCR on paraffin-embedded tissue. On the other hand, some cases may show predominance of diminute parasitic yeast forms which may be taken by those of *H. capsulatum*. Diagnosis then should rely on culture or on the use of immunohistochemistry with specific polyclonal or monoclonal anti-*P. brasiliensis* antibody.

Residual lesions of the pulmonary primary complex of the disease have rarely been described (Londero 1986; Angulo-Ortega and Pollak 1971) and they may present as fibrogranulomatous, fibrocaseous, and calcified lesions in the lungs and/or in the regional lymph nodes.

In old inactive fibrotic lesions, the remaining fungi have the morphology of nonviable cells and require a long time to multiply in microaerophilic conditions, which could explain the long latency period needed for the mycosis to become manifested in the chronic form patients (Restrepo 2000).

Immunohistochemical techniques and monoclonal antibodies to T-lymphocyte subsets have been used to characterize the tegumentary and lymphatic granulomatous lesions from patients with paracoccidioidomycosis. In the granuloma, T cells formed a peripheral mantle around the centrally aggregated macrophages. The majority of the lymphocytes were T-helper cells with few suppressor cells, indicating that those cells were actively involved in the pathogenesis of the lesions and in disease control. The phagocytic histiocyte is lys+ S-100−, whereas the antigen-presenting histiocyte is lys− S-100+. In the granulomata, the histiocyte population was predominantly lys+ with few S-100+ cells, a pattern similar to that of other immunogenic granulomata. It is possible that the interplay between antigen-presenting cells and lymphocytes in *P. brasiliensis* granuloma would result in the release of T-cell stimulating factors, such as IL-2. Lymphokines released by activated lymphocytes would attract, fix, and activate macrophages in the inflammatory foci. The activated macrophages would then show enhanced killing of *P. brasiliensis*, secrete cytokines, and further differentiate into epithelioid cells. Altogether, the effector cells in the *P. brasiliensis* granuloma are: natural killer cells, lymphocytes, T-cytotoxic cells, activated neutrophils and eosinophils, activated macrophages, epithelioid cells, giant cells, and B-lymphocytes (Moscardi-Bacchi et al. 1989).

In accordance with these data, studies on protective immunization in paracocciciodomycosis have indicated a positive correlation between elevated cellular immune responses and restriction of infection and in the numbers of fungal cells in granulomata (Meira et al. 1996).

ETIOLOGIC AGENT

Penicillium marneffei is the only species known to be dimorphic among the over 200 described species of the genus *Penicillium*. This fungus is currently only known to be endemic in southeast Asia. It can cause infections of the reticuloendothelial system in humans and lower animals.

Infections have been reported in apparently immunocompetent subjects but, more often, in immunocompromised patients undergoing corticosteroid treatment or affected by such underlying diseases as tuberculosis, Hodgkin's lymphoma and the acquired immunodeficiency syndrome (AIDS). The interest of medical mycologists in this mycosis has increased since it appeared in association with human immunodeficiency virus (HIV) infections in patients traveling or living in southeast Asia. As a result of the recent enormous increase of HIV infection in that region, *P. marneffei* has become one of the principal new emerging fungal pathogens. The disease that it causes is also known as penicilliosis marneffei.

HISTORY

P. marneffei was first described by Capponi et al. in 1956 as an etiological agent infecting the reticuloendothelial system of Chinese bamboo rats (*Rhizomys sinensis*). It was isolated by Capponi from the hepatic lesions of one of the Chinese bamboo rats maintained in captivity for experimental infections at the Pasteur Institute of Indochina at Dalat (now Vietnam). The organism was identified as a new species by Segretain (1959a), who named the fungus *Penicillium marneffei* in honor of Hubert Marneffe, then Director of the Pasteur Institute of Indochina. In the same year, Segretain (1959b) also described the first human infection that was caused by the accidental puncture of his finger by a needle used to inoculate hamsters. Nine days later, a small nodule appeared at the site, followed by lymphangitis and axillary adenopathy.

The first spontaneous infection in a human was reported in 1973 in an American minister with Hodgkin's disease, who had traveled in southeast Asia one year before (Di Salvo et al. 1973). *P. marneffei* was incidentally found in an isolated splenic abscess when the patient underwent splenectomy for management of a lymphoma. The fungus was isolated from the spleen and observed in histological sections.

A second imported case in the USA was described in a 59-year-old man who had traveled extensively in the Far East. The disease, a focal pulmonary infection, was recognized following pneumonectomy one month before death (Pautler et al. 1984).

In the same period penicilliosis marneffei was reported in southeast Asia in subjects living in Thailand (Jayanetra et al. 1984), Hong Kong (So et al. 1985; Yuen et al. 1986), and the Guangxi region of southern China (Deng and Connor 1985; Wei et al. 1985). Most of the cases in the Guangxi region were observed between 1964 and 1983 and had been originally misdiagnosed as histoplasmosis capsulati (Deng and Connor 1985).

During the period 1988–89, disseminated *P. marneffei* infections began to be observed in AIDS patients who had traveled to or were living in southeast Asia (Ancelle et al. 1988; Peto et al. 1988; Piehl et al. 1988; Coen et al. 1989; Sathapatayavongs et al. 1989; Stern et al. 1989). The recent rapid rise in the number of reported cases of penicilliosis marneffei coincides with the explosive epidemic of AIDS in northern Thailand where this mycosis is now estimated to be the third most common HIV-related opportunistic infection after tuberculosis and cryptococcosis.

With the aim of identifying the natural habitat of *P. marneffei* and its mode of transmission, several studies on wild bamboo rats have been carried out in different regions of southeast Asia where most patients with autochthonous infection have been observed (Deng et al. 1986, 1988; Wei et al. 1987; Li et al. 1989; Ajello et al. 1995; Chariyalertsak et al. 1996b).

Figure 1 *The hoary bamboo rat* Rhizomys pruinosus **(a)** *(reproduced, with permission, from Nowak 1991) and the large bamboo rat (*Rhizomys sumatrensis*)* **(b)** *(Chariyalertsak et al. 1996b).*

EPIDEMIOLOGY

Ecology

The natural habitat of *P. marneffei* is probably soil. Since the first discovery of *P. marneffei* as an agent of disease of captive wild Chinese bamboo rats (*Rhizomys sinensis*) in Vietnam (Capponi et al. 1956), these rodents have been erroneously regarded by some investigators as a potential source of human infection.

Epidemiologic investigations were therefore focused on wild rodents in the Asian areas where the disease was suspected to be endemic (Deng et al. 1986, 1988; Wei et al. 1987; Li et al. 1989; Ajello et al. 1995; Chariyalertsak et al. 1996b). The animals were trapped and portions of their internal organs cultured. Table 1 lists the bamboo rat species trapped in different Asian countries and found positive for *P. marneffei*. The most studied animals are hoary bamboo rats (*Rhizomys pruinosus*), which have been found to be apparently healthy carriers of the fungus (Figure 1). Among the internal organs, the lungs had the highest positivity (89–83 percent), followed by the liver (83–33 percent), spleen (78 percent), mesenteric lymph nodes (39 percent) and pancreas (33 percent) (Deng et al. 1986; Ajello et al. 1995).

The isolation of the fungus from four species of bamboo rats in China, Thailand, and Vietnam confirmed the value of these wild rodents as epidemiologic markers. However, there is no evidence that the disease is transmitted to humans by the bamboo rat because

a) *P. marneffei* were isolated from three of 10 reddish-brown *C. badius*. All 51 grayish-black *C. badius* were negative for *P. marneffei*.

these animals live far away from humans in remote mountain areas where few people reside (Deng et al. 1986). In addition, few people are in contact with, or consume, them. Both humans and bamboo rats are probably infected from a common environmental source. *P. marneffei* was isolated from soil collected from the burrows of hoary bamboo rats in China by Deng et al. in 1988 and in Thailand by Chariyalertsak et al. (1996b) from the burrow of *R. sumatrensis*. The modified flotation method (Vanittanakom et al. 1995) combined with mouse inoculation was applied in the isolation in Thailand.

By the analysis of 550 patients with disseminated *P. marneffei* infection diagnosed at Chiang Mai University Hospital in northern Thailand between 1991 and 1994, a consistent significant seasonal variation in the incidence of penicilliosis marneffei was observed. The infection was significantly more frequent in the rainy season (May to October) than in the dry season (Chariyalertsak et al. 1996a).

A case-control study performed in the same region did not suggest bamboo rats as a reservoir for infection in humans, nor could a significant association be demonstrated between *P. marneffei* infection and exposure to bamboo, a plant commonly growing in rural areas in northern Thailand and often eaten by Thais (Chariyalertsak et al. 1997). This study identified an age range of 16–30 years and occupational or other exposure to soil, especially during the rainy season, as factors independently associated with an increased risk for *P. marneffei* infection.

Infection in humans

The route of acquisition of *P. marneffei* has not yet been definitively established, but a respiratory portal of entry would be consistent with infections caused by other dimorphic fungal pathogens that produce conidia in their saprophytic habitats in nature. The attachment of *P. marneffei* conidia to the bronchoalveolar epithelium is facilitated by the recognition of extracellular matrix proteins, laminin and fibronectin, by a protein present on the surface of the conidia (Hamilton et al. 1999).

Studies of bamboo rats and human infections with *P. marneffei* have indicated that this organism is endemic in Thailand, the Guangxi region of China, Hong Kong, Vietnam, and Indonesia (Ajello et al. 1995). It is also suspected to be endemic in neighboring countries such as Cambodia, Laos, Malaysia, Myanmar (Burma), and, as recently reported, the Manipur State of India (Singh et al. 1999) and Taiwan (Hsueh et al. 2000). A specific skin test would be extremely useful to establish the precise geographical distribution of *P. marneffei*.

Penicilliosis marneffei has been associated with living in rural areas and with predisposing factors in the human hosts, such as cell-mediated immunodeficiency caused by lymphoproliferative disorders, corticosteroid treatment, and, most importantly, HIV infection (Drouhet 1993).

This fungal disease was a rare event in southeast Asia until the end of the 1980s (Table 2) when it began to be reported in some patients affected with AIDS who were living or had been traveling in the Asian endemic regions (Ancelle et al. 1988; Peto et al. 1988; Piehl et al. 1988; Coen et al. 1989; Sathapatayavongs et al. 1989; Stern et al. 1989). But it was from 1991, with the spread of the AIDS pandemic across the endemic areas, that *P. marneffei* emerged as a significant pathogen among HIV-infected Asian natives, especially in Thailand where the mycosis is accounting for 15–20 percent of all AIDS-related illness (Supparatpinyo et al. 1998). The disease was designated an indicator of AIDS by the Thai Ministry of Public Health (Patamasucon 1992). The possibility of spread of the fungus to the nearby nonendemic countries, as suggested in a report from Taiwan (Hsueh et al. 2000), is worrying. Penicilliosis marneffei will remain a significant public health problem in those endemic Asian countries where the incidence of AIDS is foreseen to continue its dramatic rise. At times, this fungal infection has been reported in Europe and in other nonendemic countries (Table 3). Some of the patients were native of, or had been living in, southeast Asia, but most of them had just been visiting the endemic areas for a short period of time, suggesting that exposure to the fungal propagules is probably high and the infection may be easily acquired. A non-Asian case in a Congolese HIV-positive physician suspected to have acquired penicilliosis during a training course at the Pasteur Institute in Paris (France), although not working directly with the fungus, was considered suggestive of the highly infective nature of *P. marneffei* airborne conidia (Hilmarsdottir et al. 1994). A second case in a patient native of Ghana and living in Germany, who had never been to Asia and for whom the possible source of contamination has not been found, arouses the suspicion that other natural habitats outside Asia might exist (Lo et al. 2000). Attempts to identify different genotypes of strains isolated from human and natural sources have been undertaken (Vanittanakom et al. 1996; Hsueh et al. 2000; Imwidthaya et al. 2000; Trewatcharegon et al. 2001). Further studies, however, are needed to analyze the existence of multiple genotypes of *P. marneffei* and their geographical variations.

From the history of heterochthonous cases, it appears that the period between infection in the endemic areas and manifestation of clinically active disease is extremely variable, ranging from a few weeks to 11 years, which suggests reactivation in the presence of immunosuppression (Peto et al. 1988; Jones and See 1992).

Penicilliosis marneffei occurs mainly in adults; however, cases have also been reported in children with or without AIDS, living in endemic areas (Jayanetra et al. 1984; Deng and Connor 1985; Yuen et al. 1986;

a) Non-AIDS patients.

Deng et al. 1988; Sirisanthana and Sirisanthana 1993; Kwan et al. 1997). *P. marneffei* infection appears to be an important problem in children who acquired HIV infection perinatally (Sirisanthana and Sirisanthana 1995). The clinical presentation of this mycosis in children is reported to be similar to the infection in adults.

MYCOLOGY

Morphology and physiology

P. marneffei grows in culture at 25°C on Sabouraud's dextrose agar as a mycelial fungus typical of the genus, producing rapidly growing greenish–yellow sporulating colonies, with a pink or red center and dark green edges. A characteristic brick-red pigment is released into the medium. On potato dextrose agar or Sabouraud's dextrose agar the pigment appears after 24–72 hours of incubation at 25–30°C (Figure 2). Little or no pigment is produced at 35–37°C. At this higher temperature colonies are glabrous, off-white, and yeast-like.

Microscopically, the mycelial form of growth is characterized by sinuous smooth-walled conidiophores (diameter 1.5–2 μm, length 70–100 up to 175 μm), borne on aerial hyphae, which have terminal, typically divaricate, verticils, either symmetrical or asymmetrical and seldom ramified (Figure 3). Metulae (7–11 × 2.5–3.5 μm) originate from the apex of the conidiophore in groups of four to five. Sometimes one of the metulae is much longer than the others and is usually septate. The phialides, arranged in verticils of four to six, are the same size as the metulae, and have a flask-like shape gradually tapering to a slender collar. Conidia are ellipsoidal to globose (2–3 μm), smooth walled, often with prominent disjunctors, and arranged in short disordered chains. The terminal conidia of the conidial chains are sometimes larger than the ones beneath them, which is a characteristic of *P. marneffei* (Corda's phenomenon) (Segretain 1959b).

P. marneffei requires an organic source of nitrogen for mycelial growth in a well-defined, synthetic, chemical medium. Casein hydrolysate, peptone, and asparagine are utilized, whereas $NaNO_3$ and $(NH_4)_2PO_4$ are not. Glucose (optimal growth), lactose, xylose, maltose, levulose, and mantel are used as carbon sources. Sucrose is weakly used (Segretain 1959a). The fungus is sensitive to cycloheximide. *P. marneffei* has proved difficult to maintain in culture, and pigment production may be reduced by prolonged storage. More extensive study of the biochemical properties of *P. marneffei* and their possible use in strain biotyping has been reported (Wong et al.

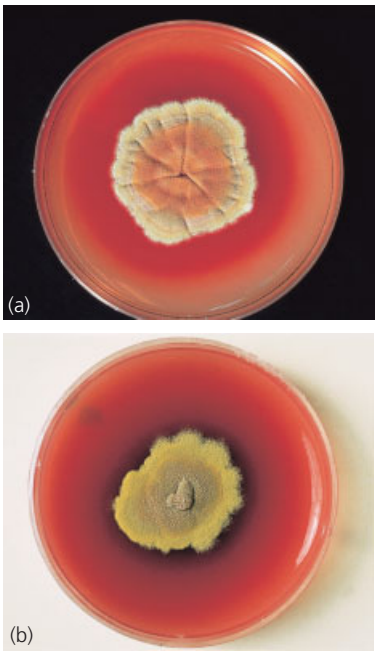

Figure 2 *Colony of* Penicillium marneffei *on* **(a)** *Sabouraud's dextrose agar and* **(b)** *potato dextrose agar after 10 days of incubation at 28°C*

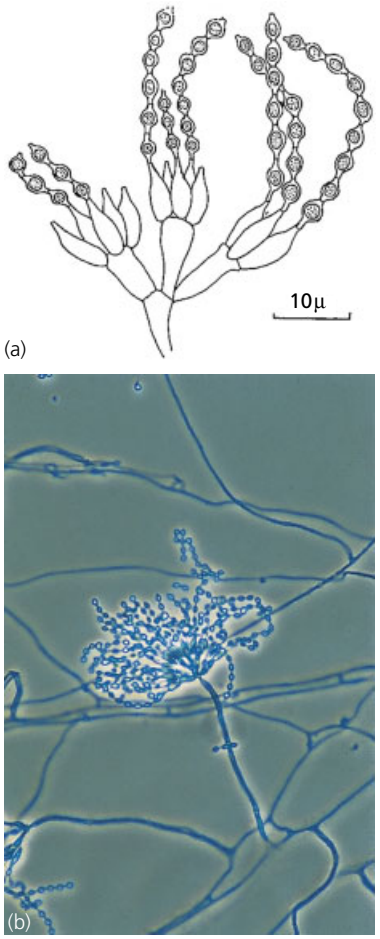

Figure 3 *Conidiophore of* Penicillium marneffei *from Segretain's drawing of the type strain* **(a)** *and microscopy of the mold form of this fungus (lactophenol cotton blue mount)* **(b)**. *Magnification, × 600*

2001a). In addition, some enzymatic activities were examined in *P. marneffei* human isolates (Youngchim et al. 1999). Both mycelial and yeast form expressed several interesting enzymes, for examples, acid phosphatase, esterases, and lipases, which might be implicated with virulence in this fungus.

The fungus is characterized by its thermal dimorphism. When grown at 37°C on 5 percent sheep blood agar, wort agar, or in liquid synthetic media containing maltose or glucose and amino acids, *P. marneffei* undergoes a transformation to a yeast-like single-cell form, also named arthroconidium.

Hyphae first become shorter, develop more septa and branches, and cease to produce conidia. After 2 weeks there is a gradual shift to spherical or ellipsoidal yeast-like cells which are 2–6 μm in diameter and divide by transverse septation (fission) in a somewhat similar fashion to *Schizosaccharomyces* spp.

The in vitro yeast-like form resembles that found in rodents and humans. Globose, ovoid, and elongated yeast-like cells measuring 2–3 × 2–6.5 μm are seen free and within macrophages. Extracellular, elongated, and sausage-shaped cells up to 8–13 μm long, and more rarely short hyphae, no longer than 20 μm, are also observed. The multiplying cells usually have a single central septum and occasionally two.

The cells of *P. marneffei* are poorly stained by hematoxylin and eosin (H&E). Their cell wall, however, is well stained by periodic acid–Schiff (PAS) and Gomori's methenamine silver (GMS) stains. Initially, *P. marneffei* yeast forms were mistaken for *Histoplasma capsulatum* var. *capsulatum* yeast cells (Deng and Connor 1985). The principal differences between the tissue forms of these two dimorphic fungi are presented in Figures 4 and 29.5.

The ultrastructural characteristics of *P. marneffei* in golden hamsters were described by Drouhet and colleagues who showed the evolution of the fungal cell in liver macrophages (Drouhet et al. 1988). The various stages of the multiplication process (formation of the septum and division by fission) were recognized (Figure 6). The yeast-like cells were often included in phagolysosomes, and some were surrounded by concentric calcified layers as in an onion bulb. This aspect of the host defense reaction has also been observed in animal models and human infections caused by *Histoplasma capsulatum* var. *capsulatum*.

Identification

In the first mycological description of *P. marneffei* (Segretain 1959a), the new species was classified in the genus *Penicillium*, section Asymmetrica, subsection Divaricata, according to Raper and Thom's classification (Raper and Thom 1949). Subsequently, however, *P. marneffei* was assigned to the subgenus Biverticillium of

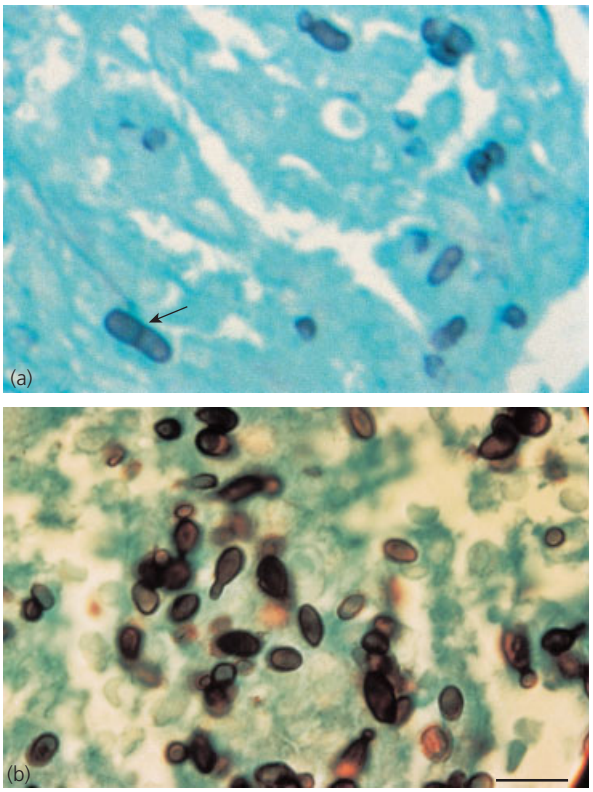

Figure 4 (a) *Oval, round, and sausage-shaped cells of* Penicillium marneffei, *some with septum (arrows), in a tissue section.* **(b)** *Uniform round and ovoid budding cells of* Histoplasma capsulatum *var.* capsulatum *in a tissue section. GMS stain; bar, 10 μm.*

Pitt's taxonomy because of its frequently biverticillate conidiophores and on the basis of its poor growth on 25 percent glycerol nitrate agar (Pitt 1979). Phylogenetic analysis also confirmed that *P. marneffei* is closely related to the *Penicillium* species in the subgenus *Biverticillium*, and the sexual *Talaromyces* species with an asexual biverticillate penicillium state (LoBuglio and Taylor 1995).

The above-described macro- and micromorphology of *P. marneffei* is relatively characteristic, and identification of the fungus is not considered difficult. A reddish pigment is, however, produced by other *Penicillium* species from which *P. marneffei* must be differentiated (Table 4).

Another approach to the differentiation of *P. marneffei* from other penicillia consists of the use of an exoantigen test (Sekhon et al. 1989). The exoantigen extract from a slant culture of *P. marneffei* is tested by a reverse microimmunodiffusion procedure against rabbit anti-*P. marneffei* reference serum in the presence of appropriate reference antigens. The production of two precipitin lines of the same identity as the *P. marneffei* reference system confirms identification.

A significant criterion in the identification of this fungus is based on the observation that *P. marneffei* is the only species of the *Penicillium* genus which, on enriched media at 37°C, converts into a schizogenous yeast form.

HOST RESPONSES

Clinical presentation

The clinical presentation of penicilliosis marneffei is similar in patients with and without HIV infection. Predominant signs and symptoms are chills, persistent fever, lymphadenopathy, hepatosplenomegaly, leukocytosis, anemia, persistent cough, weakness, and weight loss. Skin lesions and subcutaneous abscesses have often been reported. This clinical presentation is relatively nonspecific. It may be suggestive of tuberculosis or other systemic mycoses. Patients with AIDS present similar manifestations caused by HIV as well as other opportunistic infections or lymphoma.

P. marneffei usually causes an invasive disseminated disease, characterized in AIDS patients by a more rapid onset and more severe symptoms. Focal infections have been described rarely. The spleen, lung, or nasopharynx

Table 4 *Main characteristics of* Penicillium *spp. producing reddish diffusible pigments*

P. rubrum	*Biverticillatum*	Biverticillate symmetrical appressed	Smooth	Red to purple–red

was reported as the only involved organ in HIV-negative patients (Di Salvo et al. 1973; Pautler et al. 1984; Deng et al. 1988; Chan et al. 1989). Among the AIDS population, one patient was reported to have a localized *P. marneffei* infection of the lung, which was diagnosed in the very early stage by a normal chest x-ray (Romaña et al. 1989).

Data on the extent of organ involvement are incomplete because several cases have been poorly described. An analytical overview of the clinical aspects of the first 88 cases, half of them in AIDS patients, has been published (Drouhet 1993). Pulmonary manifestations, mostly persistent cough and dyspnea, and occasionally chest pain and hemoptysis, associated with bronchopneumonia, pulmonary abscess or pulmonary infiltrates, have been reported in 70 percent of HIV-negative and 86 percent of HIV-positive patients. In some cases, however, respiratory involvement has been found in the presence of a normal chest x-ray. In addition to lymphadenopathy in 45–56 percent of patients and hepatosplenomegaly in 43–50 percent, lesions have frequently been observed in other body sites such as the meninges, kidney, pericardium, and digestive tract – expressions of hematogenous spread of the infection.

Cutaneous and subcutaneous involvement has been reported in 68–71 percent of patients with or without AIDS (Supparatpinyo et al. 1994; Drouhet and Dupont 1995). Papules, rashes, acne-like pustules, and nodules are usually multiple, and located on the face, trunk, and extremities. Some of the papules have central necrotic umbilications resembling molluscum contagiosum (Figure 7). A more rapid appearance of multiple cutaneous lesions is observed in AIDS patients.

Bone and joint infections have also occurred in patients with disseminated disease, affected or not with AIDS (Jayanetra et al. 1984; Deng and Connor 1985; Chan and Woo 1990; Li et al. 1991; Louthrenoo et al. 1994; Deng and Ma 1995; Pun and Fang 2000). Arthritis affected both the large peripheral joints and the small finger joints, and osteomyelitis affected the flat bones of the skull, ribs, and the long bones. Most of the patients had multiple osteolytic lesions associated with swelling of the soft tissue and pain, particularly of the joints.

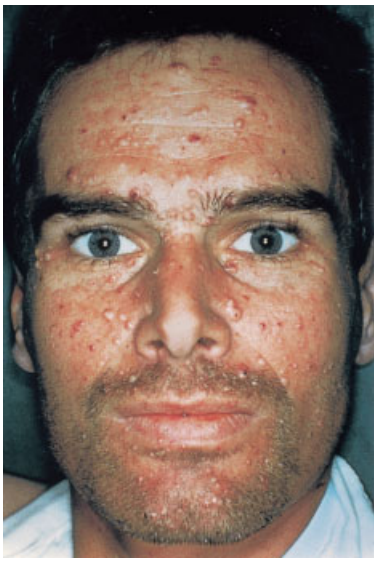

Figure 7 *Skin lesions in HIV-positive patient infected with* Penicillium marneffei. *Some of the papules have a central umbilication resembling lesions of molluscum contagiosum. (Reproduced, with permission, from Kronauer et al. 1993)*

Histopathology

The host response to *P. marneffei* invasion mainly involves the mononuclear phagocytic cells of the lung and the reticuloendothelial system, and resembles the response in acute histoplasmosis capsulati. In the early lesions, *P. marneffei* yeast-like cells are engulfed by histiocytes where they proliferate within the phagocyte's vacuoles. As the lesions progress, necrosis develops in the central areas, and fungal cells are released into the cytoplasm. Infiltration of neutrophils is followed by abscess formation. A granulomatous reaction takes place, especially in the organs of the reticuloendothelial system, with epithelioid cells, lymphocytes, plasma cells, and giant cells surrounding the necrotic area. Slowly evolving granulomas in the lung may lead to fibrosis and cavitation. Calcifications, such as those seen in experimental and human pulmonary histoplasmosis capsulati, have not been observed in human patients with

penicilliosis marneffei, but have been reported in liver macrophages of experimentally infected golden hamsters (Drouhet et al. 1988). The fungal cells were surrounded by concentric calcified layers like onion bulbs, which represented a host defense response.

A totally different histopathological pattern – an anergic and necrotizing reaction involving mainly the lung, liver, and skin – is associated with compromised immunity of the host. The reaction is characterized by necrosis surrounded by histiocytes, which are distended by the engulfed proliferating fungi and are unable to form phagocytic vacuoles. This histopathological feature indicates a progressive disseminated infection.

In anergic as well as in pyogranulomatous lesions, special stains such as PAS or GMS are essential to distinguish penicilliosis marneffei from tuberculosis and other systemic mycoses as the fungi stain poorly in H&E preparations.

Immunology

The inhaled *P. marneffei* conidia are known to recognize fibronectin and to bind laminin of the bronchoalveolar epithelium via a sialic acid-containing receptor, avoiding entrapment by the mucus and removal from the respiratory tract (Hamilton et al. 1999). This adherence represents the first step of the host–parasite interaction. After attachment to the bronchoalveolar epithelium, *P. marneffei* conidia are easily phagocytized by macrophages.

The response of phagocytic cells to *P. marneffei* was studied with a macrophage culture system, using murine J774 macrophages and culture conditions suitable to reproduce the transformation of the fungus from the conidial to the characteristic in vivo yeast-like form. The results showed that following phagocytosis of *P. marneffei* conidia, nonstimulated murine macrophages are damaged by the fungus, which, growing intracellularly, undergoes transformation into a yeast-like form. By contrast, macrophages stimulated with interferon-gamma (IFN-γ) (50 U/ml) and lipopolysaccharide at 1 μg/ml significantly inhibit the intracellular growth of the conidia and kill the fungus. This correlates with the amount of nitric oxide produced by stimulated macrophages, suggesting that the L-arginine-dependent nitric oxide pathway has an important role in the murine host defense against *P. marneffei* (Cogliati et al. 1997). Killing of intracellular *P. marneffei* conidia was also shown to occur in IFN-γ-lipopolysaccharide-activated human THP1 cells (Taramelli et al. 2000). An increase in pH within the phagocytic vacuole, by threatening the *P. marneffei*-infected human THP1 and mouse J774 macrophages with chloroquine, induced macrophage killing of this fungus (Taramelli et al. 2001). The increase in intravacuolar pH may directly reduce fungus growth or may inhibit pH-dependent yeast virulence factors. It has been shown that both mycelial and yeast form of *P. marneffei* expressed acid phosphatase activity (Youngchim et al. 1999). This enzyme has been considered one of the virulence factors for intracellular pathogen (Baca et al. 1993).

Other polymorphonuclear (PMN)-activating cytokines have been proven to enhance PMN inhibitory effects on germination and morphological changes of *P. marneffei*, but only granulocyte-macrophage colony stimulating factor (GM-CSF), granulocyte colony stimulating factor (G-CSF), and IFN-γ enhance PMN activity from being fungistatic to fungicidal (Kudeken et al. 1999). The killing mechanism of GM-CSF-stimulated neutrophils on *P. marneffei* was not mediated by a superoxide-dependent mechanism, but through exocytosis of granular enzymes which were largely heat-labile (Kudeken et al. 2000).

The ability of unopsonized *P. marneffei* to parasitize mononuclear phagocytes without stimulating the production of tumor necrosis factor (TNF)-alpha, observed in vitro using human leukocytes, may be critical for host defenses as it enhances the virulence of this intracellular parasite (Rongrungruang and Levitz 1999).

Iron availability was reported to affect the immunity to, and the pathogenicity of, *P. marneffei*, as iron overloading significantly reduces the antifungal activity of macrophages, whereas exogenous iron enhances, and iron chelators inhibit, the extracellular growth of *P. marneffei* (Taramelli et al. 2000).

It was shown that the immunocompetent host generates a cell-mediated response against *P. marneffei* (Deng et al. 1988) and that the failure of a CD4+ T-cell-dependent immunity in AIDS patients contributes to the development of disseminated systemic infection (Viviani and Tortorano 1990; Supparatpinyo et al. 1992).

The role of T lymphocytes in host defenses against *P. marneffei* was studied in mice experimentally depleted of CD4+ or CD8+ T cells (Viviani et al. 1993a). The results suggest that CD4+ T cells and, to a lesser extent CD8+ T cells, play a role in the protective host response against the fungus. *P. marneffei* strains differed in their virulence for mice. Depending on this virulence, CD4+ T-cell-mediated protective immunity acts to slow or halt multiplication of the fungus in the viscera. It is therefore likely that AIDS patients are susceptible to systemic *P. marneffei* infection because they are unable to generate a CD4+ T-cell response. Furthermore, CD8+ T cells, which are spared by the virus, may be insufficient to eliminate the organisms in developing granulomas. Further evidence that cell-mediated immunity plays a central role in a host defense mechanism against *P. marneffei* infection was provided in work involving experimentally infected mice (Kudeken et al. 1996).

In the mouse model, CD4+ T cells play an important role in eradicating *P. marneffei* from infected sites (Kudeken et al. 1997). Interleukin-12 (IL-12) protects mice against this infection. The induction of IL-12

synthesis by human peripheral blood mononuclear cells is promoted by a phosphoprotein, osteopontin (OPN), after stimulation with *P. marneffei* (Koguchi et al. 2002). Furthermore, the OPN production by monocytes is regulated by GM-CSF. It is suggested that the possible mechanism is mediated by mannoprotein in the OPN production upon stimulation by *P. marneffei*. The mannoprotein (Mp1p) is known as an abundant cell wall antigen of the yeast cells of this fungus (Cao et al. 1998a). Thus, the OPN may promote a Th1 response through the mannoprotein-induced IL-12 secretion by human macrophages stimulated with *P. marneffei* and contribute to host defense against this pathogen. In addition, IFN-γ renders murine macrophages highly active in killing *P. marneffei* yeast cells by promoting the release of nitric oxide (Kudeken et al. 1998).

LABORATORY DIAGNOSIS

The high mortality rate in the first reported cases of *P. marneffei* infection is attributable to a delay in diagnosis because the mycosis was often misdiagnosed as tuberculosis and treated accordingly. The recently improved survival rate can be ascribed to clinicians' and microbiologists' increased awareness of the disease.

Diagnosis rarely requires invasive procedures even though biopsy of lymph nodes, lung, liver, and bone marrow provides specimens rich in fungal organisms trapped by the reticuloendothelial cells. Biopsy is recommended in the presence of skin nodules or subcutaneous abscesses. Skin lesions should be sought carefully because they may facilitate diagnosis. Biopsy samples must always be processed for both microscopy and culture. Other laboratory tools including polymerase chain reaction (PCR) and methods for detecting specific antibody against and antigen of the fungus in clinical specimens have been developed.

Microscopic examination

A variety of clinical specimens is appropriate to diagnose this condition. The clinical specimens include bone marrow aspirates, blood, lymph node biopsies, skin biopsies, skin scrapings, sputum, bronchoalveolar lavage pellets, pleural fluid, liver biopsies, cerebrospinal fluid, pharyngeal ulcer scrapings, palatal papule scrapings, urine, kidney, pericardium, stomach or intestine, and stools (Vanittanakom and Sirisanthana 1997). Rapid bedside diagnosis can be made by microscopic examination of Wright's stained bone marrow aspirates and/or touch smear of skin biopsy or lymph node biopsy specimens (Supparatpinyo et al. 1994). The yeast cells of *P. marneffei* could be seen in the peripheral blood smear of a patient with fulminant infection (Supparatpinyo and Sirisanthana 1994).

P. marneffei can be seen in histopathological sections stained with H&E, GMS, or PAS. They must be discriminated from *Leishmania donovani*, *Pneumocystis carinii*, and *Histoplasma capsulatum* var. *capsulatum*, which also frequently cause disease in patients with AIDS. *P. marneffei* superficially resembles the *H. capsulatum* var. *capsulatum* in tissue when yeast-like cells are clustered within macrophages or histiocytes, but the two organisms multiply differently. *P. marneffei* replicates by fission, instead of budding, and the considerable variation in size and shape of the extracellular yeasts (enlarged, occasionally septate, tubular or sausage shaped) makes *P. marneffei* easily distinguishable from the budding tissue-form cells of *H. capsulatum* (see Figures 4 and 5).

A specific indirect fluorescent antibody reagent was developed to facilitate the rapid detection and identification of *P. marneffei* in histological sections (Kaufman et al. 1995). This antiglobulin preparation has proved to be specific because it failed to react with the yeast and hyphal forms of *H. capsulatum* and with a variety of other fungi, including *Aspergillus* spp. Specific IgM monoclonal antibodies were also produced from mice immunized with *P. marneffei* mycelial culture filtrate and proven strongly reactive in immunofluorescence staining of the fungus in tissue samples (Trewatcharegon et al. 2000).

Cultures

P. marneffei can be cultured from various clinical specimens. Bone marrow culture is the most sensitive (100 percent), followed by skin biopsy culture (90 percent), and blood culture (76 percent) (Supparatpinyo et al. 1994). A blood culture method, the lysis centrifugation system (Isolator System, Wampole Laboratories, Cranbury, NJ), has proved highly effective for the isolation of *P. marneffei*, especially in AIDS patients who frequently have concomitant bacteremia.

P. marneffei grows easily in routine culture media containing antibacterial agents. The fungus is inhibited by cycloheximide, which has therefore to be excluded from Sabouraud's dextrose agar. Inoculated Petri dishes should be incubated at 25°C and 37°C to demonstrate thermal dimorphism. The fungus grows in a mycelial phase at 25°C after 3–5 days of incubation. The mycelial phase produces red pigment which diffuses into the agar (Figure 2). Aged colonies are deep red. Microscopic examination shows typical structure of the genus *Penicillium* (see Figure 3). At 35–37 C° on Sabouraud's agar or on brain–heart infusion agar, colonies are glabrous, off-white and yeast like, and the diffusible red pigment may be poorly produced (Figure 8, Figure 9). Pigment may also be masked by the color of media such as blood or chocolate agar. Microscopically, yeast cells of *P. marneffei* are

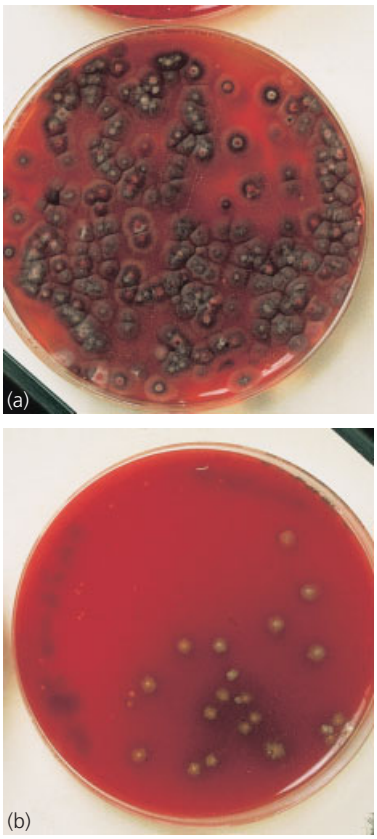

Figure 8 *Colonies of* Penicillium marneffei *grown from blood (Isolator system blood culture) on* **(a)** *Sabouraud's dextrose agar and* **(b)** *blood agar, after 7 days at 37°C.*

globose to oval with single septum, or arthroconidia-like cells.

Serodiagnosis

ANTIBODY DETECTION

Several studies were carried out to detect reliable reagents for antibody and antigen detection in body fluids. Although antigen is more likely to be detected than antibodies in patients with impaired immunity, antibodies to *P. marneffei* were shown to be produced by AIDS patients and may be useful for monitoring the efficacy of treatment. A microimmunodiffusion test, using a mycelial culture filtrate antigen of *P. marneffei* (Sekhon et al. 1982), has been used to monitor the serological response of an AIDS patient with penicilliosis marneffei (Viviani et al. 1993b). Sera drawn early in the course of the disease gave positive antibody reactions whereas sera taken 3–5 months after the start of therapy were negative. In another study of the immunodiffusion test, using yeast culture filtrate antigen, only two of 17 patients infected with *P. marneffei* were positive antibody reactions in their serum specimens (Kaufman et al. 1996). An indirect fluorescent antibody test for detecting IgG antibody, using germinating conidia and yeast cells as antigens (Yuen et al. 1994), could detect the IgG titer of 160 or more in patients infected with *P. marneffei*.

Thereafter, several tests to detect antibodies to *P. marneffei* have been developed using crude antigen preparation from yeast phase and mold phase, purified proteins from yeast phase, and recombinant antigen. An immunoblot analysis of sera from 33 *P. marneffei*-infected AIDS patients, 29 non-infected AIDS patients, 25 AIDS patients from nonendemic areas, and 84 healthy individuals revealed the specificity of secreted yeast phase proteins of 54 and 50 kDa in the diagnosis of penicilliosis marneffei (Vanittanakom et al. 1997). Other diagnostic antigens of *P. marneffei* included antigens with relative molecular masses of 61 kDa (Jeavons et al. 1998) and 38 kDa (Chongtrakool et al. 1997), which were prepared from purified cytoplasmic yeast antigen and from acetone-precipitated culture filtrate of mold form, respectively. In addition, a gene (*MP1*) encoding a highly antigenic cell wall mannoprotein (Mp1p) has been cloned and the purified recombinant antigenic mannoprotein produced and tested in an

enzyme-linked immunosorbent assay (ELISA) for antibody detection (Cao et al. 1998a, b). The sensitivity of these antigenic preparations is difficult to compare as different methods have been used and different patient populations studied. Recently, recombinant Mp1p protein vaccine was used for generation of protective immune responses against *P. marneffei* infection using a mouse model, and compared with *MP1* DNA vaccine delivered by live-attenuated *Salmonella typhimurium* (Wong et al. 2002). The intramuscular *MP1* DNA vaccine offered the best protection after challenge with *P. marneffei* yeast cells intravenously.

The scanty antibody response of immunosuppressed patients or the presence of antibodies in patients previously exposed to the fungus may limit the usefulness of the antibody detection. Tests for antigen detection would be of major clinical value, mainly to diagnose promptly the infection in patients without skin lesions, to identify AIDS patients with an initial infection and to predict relapse.

ANTIGEN DETECTION

In order to assess the presence of antigen in body fluids of patients affected with *P. marneffei*, rabbit polyclonal antibodies against arthroconidial filtrate (or yeast phase) were used in an immunodiffusion and a latex agglutination (LA) test and, despite the crude antigen preparation used to raise the antibody reagent, the tests showed a surprisingly high specificity, 100 percent (Kaufman et al. 1996). Encouraging results were also obtained with the antibody reagent against the recombinant mannoprotein Mp1p, that was used to test sera from AIDS and non-AIDS patients with penicilliosis in an ELISA assay with a specificity and sensitivity of 100 and 65 percent, respectively (Cao et al. 1999). The combined use of antigen and antibody tests was proven to increase the diagnostic sensitivity from 76 to 82 percent (Kaufman et al. 1996) and from 65 to 88 percent (Cao et al. 1999). The ELISA system using the recombinant Mp1p was further tested with sera from eight *P. marneffei*-infected HIV-positive patients and seven *P. marneffei*-infected HIV-negative patients (Wong et al. 2001b). Serum antigen titers were found to be higher in HIV-positive patients, whereas serum antibody titers were found to be higher in HIV-negative patients. A urinary antigen detection assay was also studied using a rabbit hyperimmune IgG preparation which, at a cutoff titer of 1:40, had a diagnostic sensitivity of 97 percent and specificity of 98 percent (Desakorn et al. 1999). A dot blot ELISA and a LA test were developed further for detecting *P. marneffei* antigenuria by using the same polyclonal antibody and compared with the ELISA (Desakorn et al. 2002). All tests appeared to be highly specific. The sensitivities of the tests were as follows: dot blot ELISA, 94.6 percent; ELISA, 97.3 percent; and LA test, 100 percent. The LA test will be evaluated for the detection of antigenemia and for the treatment follow-up.

PCR

Oligonucleotide primers for selective amplification of *P. marneffei* DNA were designed from the nuclear ribosomal DNA (rDNA) internal transcribed spacer region (LoBuglio and Taylor 1995). Using the nested PCR, the test was 100 percent successful in amplifying *P. marneffei* DNA. Thereafter, nucleotide sequence from the 18S rDNA of this fungus was determined (Vanittanakom et al. 1998). An oligonucleotide probe was designed and proved to be specific for *P. marneffei* in the PCR-hybridization reaction, regardless of whether the fungus was isolated from humans or natural habitats. This PCR-hybridization technique could be used to detect *P. marneffei* DNA in EDTA-blood samples collected from AIDS patients with penicilliosis. Recently, new PCR primers were designed based on the 18S rDNA sequence, and were used in a single and nested PCR methods for the rapid identification of *P. marneffei* (Vanittanakom et al. 2002). Very young culture of *P. marneffei* (2-day-old filamentous colony, 2 mm in diameter) could be performed by this assay. The application of this method for early diagnosis of the disease needs to be studied further. Another method which was developed to provide rapid identification of dimorphic fungi including *P. marneffei* was a PCR-enzyme immunoassay (PCR-EIA) method (Lindsley et al. 2001). The DNA was amplified by using universal fungal primers which was directed to the conserved regions of rDNA. The PCR amplicons were then detected colorimetrically in an enzyme immunoassay format for specific fungal species. The probes developed in this test were found to be highly specific and should prove to be useful in differentiating these organisms in the clinical setting.

THERAPY

P. marneffei infection is fatal in the absence of treatment, as documented by a fatality rate of 91.3 percent in non-AIDS patients and 100 percent in AIDS patients (Drouhet 1993; Supparatpinyo et al. 1993). In addition, a high rate (50 percent) of relapse is reported after successful primary therapy (Supparatpinyo et al. 1998).

In vitro studies have shown that most *P. marneffei* strains are very sensitive to the antifungals used in systemic treatment, mostly to amphotericin B, ketoconazole, itraconazole, voriconazole, and terbinafine (Sekhon et al. 1992; Drouhet 1993; Supparatpinyo et al. 1993; Boon-Long et al. 1996; McGinnis et al. 1997, 2000).

The antifungal drugs mostly used in the treatment of *P. marneffei* infection are amphotericin B, itraconazole, and ketoconazole. At present, the treatment regimen

recommended in Thailand consists of a 2-week course of intravenous amphotericin B, followed by itraconazole (400 mg/day) for 10 weeks, given on an outpatient basis (Sirisanthana et al. 1998). The short course of amphotericin B was designed to lower the incidence of adverse drug effects and to reduce the length of hospital stay. As *P. marneffei* is highly susceptible to itraconazole, patients with mild to moderately severe infection can be given itraconazole 400 mg/day as primary therapy (Supparatpinyo et al. 1998). Secondary prophylaxis with itraconazole 200 mg/day is well tolerated and should be the standard care for patients with AIDS successfully treated for *P. marneffei* infection (Supparatpinyo et al. 1998). Itraconazole (200 mg/day) has been proved to be safe and effective as primary prophylaxis to prevent *P. marneffei* infection in patients with advanced HIV infection, especially those with CD4+ lymphocyte counts of <100 cells/μl (Chariyalertsak et al. 2002).

FUNGAL GENETICS

P. marneffei is a dimorphic fungus which displays a temperature-dependent dimorphism. In host cells or at 37°C, the fungal hyphae undergo phase transition via the arthroconidiation to form fission yeast cells. The genetic factors that express during phase transition may be involved in the molecular mechanisms of fungal cell morphogenesis and pathogenesis. A homolog of the *Aspergillus nidulans abaA* gene has been cloned from *P. marneffei* and shown that it is involved in both asexual conidiation at 25°C and dimorphic hyphal-yeast switching (Borneman et al. 2000).

Another gene, *cflA*, which is a homolog of the *Saccharomyces cerevisiae cdc42*, has been cloned from *P. marneffei* (Boyce et al. 2001). *cflA* is required for polarized growth of the vegetative mycelium at 25°C and for correct cellular morphology and separation of yeast cells at 37°C. However, it does not appear to be involved in development or in dimorphic switching. Furthermore, a *gasA* gene encoding a Gα subunit has been cloned from *P. marneffei*, and investigated as a key regulator of asexual development (Zuber et al. 2002). By contrast, *gasA* mutants have no apparent defect in dimorphic switching or yeast-like growth. Borneman et al. (2002) has cloned and characterized an APSES protein-encoding gene from *P. marneffei* that has a high degree of similarity to *Aspergillus nidulans stuA*. This gene is required for metula and phialide formation of *P. marneffei* but is not required for dimorphic growth.

A search for phase-specific genes in *P. marneffei* has been investigated by using differential display technique (Cooper and Haycocks 2000). Many of the genes whose expression displays during mold-to-arthroconidium transition are related to energy metabolism. Expression of the gene which encodes malate synthase is upregulated in the arthroconidial or yeast phase as compared to the mold phase (Cooper and Haycocks 2000). The authors plan to assess the role of those genes in the virulence of *P. marneffei* in murine model by creating specific gene-disruption mutants.

The genus *Candida* comprises about 200 species, of which close to 20 have been associated with pathology in humans or animals (Meyer et al. 1998; de Hoog et al. 2000), including species, such as *Candida famata* or *Candida inconspicua*, which have been added more recently to the list of potential pathogens. This chapter focuses only on the major pathogenic species:

- *Candida albicans*
- *Candida dubliniensis*
- *Candida glabrata*
- *Candida guilliermondii* and its teleomorph *Pichia guilliermondii*
- *Candida kefyr* and its teleomorph *Kluyveromyces marxianus*
- *Candida krusei* and its teleomorph *Issatchenkia orientalis*
- *Candida lusitaniae* and its teleomorph *Clavispora lusitaniae*
- *Candida parapsilosis*
- *Candida tropicalis*

HISTORIC NOTES

Based on detailed historic reviews of the genus *Candida* (Odds 1988; Rippon 1988; Kwon-Chung and Bennett 1992), the following significant data regarding the genus and the diseases caused by it may be outlined.

The first known description of *Candida* infection, oral candidiasis (thrush) in two patients with other underlying disease, may be found in Hippocrates' 'Epidemics' from the fourth century BC. The first descriptions of thrush in modern medicine were made by Rosen von Rosenstein in 1771 and by Underwood in 1784, who identified the infection as a pediatric problem and accordingly described it in books dealing with such entities. Veron in 1935 suggested that the gastrointestinal tract of newborns might become infected during birth. Although Lagenbeck, in 1839, described the fungus in a case of oral thrush observed in a patient suffering from typhus, he misidentified it as the causative agent of the underlying disease. The correct association between oral thrush and the fungus was made only 3 years later, in 1842, by Gruby who classified the microorganism as *Sporotrichum*.

During the following decades various pathological conditions were shown to be associated with yeasts. The fungus was isolated by Bennett in 1844 in the sputum of a tuberculotic patient, by Wilkinson in 1849 from vaginal candidiasis, by Robin in 1853 from a systemic infection and by Zenker in 1861 from a brain infection in a debilitated patient, in whom the fungus spread hematogenously from an oral infection. In 1875, Hausemann established the possibility of infant infection during birth by demonstrating the analogy between the causative agent of oral and vaginal thrush. Additional pathological entities caused by *Candida* were described at the beginning of the twentieth century: onychomycosis by Dubendorfer in 1904, dermatitis by Jacobi in 1907, chronic mucocutaneous candidiasis by Forbes in 1923, and cystitis by Rafin in 1910. Later, in 1928, Conner described osteomyelitis, in 1940 Joachim and Polayes

described endocarditis, and in 1943 Suthin noted the association between pathology of the endocrine system and *Candida* infections. Castellani, in 1912, while describing 'tea tasters' cough,' was probably the first to suggest the possibility that *Candida* species other than *C. albicans* may be involved in pathological processes.

The nomenclature of the yeast isolated from the patients, changed often. Robin in 1853 named it *Oidium albicans*, Quinquad in 1868 *Syringospora robinii*, and Reess in 1875 *Saccharomyces albicans*. Mycological studies by Grawitz, published in 1877, described the various morphological forms of *Candida*. The first binomial to gain wide acceptance over a long period, and which is sometimes still used, albeit wrongly, was *Monilia albicans*, which was suggested by Zopf in 1890. The criteria defined by Saccardo for the genus *Monilia* permitted the inclusion of certain fungi isolated from rotting vegetation into the genus. Berkhout, in 1923, after recognizing the differences between *Monilia* spp. isolated from rotting plants and fruit and those isolated from medical cases, established the genus *Candida* to accommodate the latter. This was accepted as the official name of the genus by the Eighth Botanical Congress in Paris in 1954.

Two major medical events have revived the interest in fungal diseases in general and *Candida* infections in particular. The first was the introduction of antibacterial drugs in the second half of the twentieth century. These drugs, especially those having a broad spectrum of activity, may act as predisposing factors for mycotic infections by causing an imbalance of the host's natural microflora in favor of fungi, upon which they have no inhibitory activity. The second event was the increase in the prevalence of immunosuppressed patients during the last few decades, as a result of chemotherapy or disease [acquired immunodeficiency syndrome (AIDS)], which led to a parallel increase in the incidence of *Candida* infections in general, and the less pathogenic non-*C. albicans* species in particular.

These events, in conjunction with the development of more sophisticated biological research techniques, led to a highly intensive study of the pathogenic mechanisms of *Candida* infection, such as adhesion, production of proteinases, and interaction with the defenses of the host and, consequently, to new concepts for diagnosis and management. Another result of the intense interest in *Candida* was the increased demand for more efficient drugs with fewer side effects. Recent reports indicating the possibility of innate or acquired resistance of a number of *Candida* spp. to several antimycotic drugs (see section on Treatment below) has emphasized the importance of in vitro antimycotic susceptibility testing and has prompted efforts toward the standardization of these procedures and their interpretation.

The extensive use of antimycotic drugs, particularly azoles, for prolonged therapeutic courses has led to changes in the relative prevalence of various *Candida* species, with a decrease in the proportion of *C. albicans* as the etiologic agent of candididiasis and an increase in the proportion of non-*albicans* species such as *C. glabrata* or *C. krusei* (Krcmery and Barnes 2002).

An additional recent aspect is the development of molecular technologies in the use of taxonomy, resulting in changes of the status of certain *Candida* spp. and the recognition of new species such as *C. dubliniensis* by Sullivan and colleagues in 1995 (Sullivan et al. 1995; Gutierrez et al. 2002). This species was discovered in the course of an epidemiologic survey of *Candida* in human immunodeficiency virus (HIV)-positive patients. It was identified initially as an 'atypical *Candida albicans*' strain that did not hybridize with a *C. albicans* specific probe (Sullivan et al. 1993). Subsequently, it was recognized as a separate taxon (Sullivan et al. 1995).

TAXONOMIC COMMENTS

Most yeast species dealt with in this chapter often went through name changes, usually following the discovery of synonymy among species, discovery of teleomorphic stages or nonvalidity of binomials. For a comprehensive treatise on the taxonomic aspects of yeasts the reader is referred to Kurtzman and Fell (1998) and de Hoog et al. (2000).

The more recent changes in nomenclature are described below, some of them based on molecular biological methods which have been applied in search of a better understanding of taxonomic relationships between yeast species. The analysis of small ribosomal subunit sequences has shown (Barns et al. 1991; Hendriks et al. 1991) that *C. albicans*, *C. tropicalis*, *C. parapsilosis*, and *Candida viswanatii* form one subgroup with a more distant connection to *C. guilliermondii*. *C. kefyr* and *C. glabrata* are located on two different but interconnected branches, while *C. lusitaniae* and *C. krusei* are on a different branch each. These findings are in agreement with those of the coenzyme Q analysis (Yamada and Kondo 1972) which assesses the number of isoprene units per ubiquinone molecule, according to which *C. albicans* and *C. tropicalis* and *C. guilliermondii* share the same system (Q9), *C. kefyr* and *C. glabrata* share the Q6 system, whereas *C. lusitaniae* and *C. krusei* have Q8 and Q7 systems, respectively.

Candida species, exhibiting a teleomorphic stage, are considered ascomycetous fungi (Kurtzman 1993). Meyer et al. (1998) divided the *Candida* species on the basis of physiological characteristics into 12 groups. The pathogenic *Candida* species dealt with in this chapter are included in group VI. They do not assimilate inositol, erythritol, and nitrate and grow at 40°C.

Candida albicans

The most significant change in the taxonomy of this species was the acceptance of the present binomium in

place of *Monilia albicans* (see section on Historic notes below). The synonymy between *C. albicans*, *C. langeronii*, and *C. clausenii* has been confirmed by molecular biological methods (Mahrous et al. 1992; Wickes et al. 1992) as has been that of *Candida stellatoidea* (Kwon-Chung and Bennett 1992).

Two serotypes, A and B, based on differences between the mannan component of the cell wall have been described (Hasenclever and Mitchell 1961). Serotype A was found to be antigenically related to *C. tropicalis*, whereas serotype B was related to *C. stellatoidea*, currently integrated into the *C. albicans* species. Additional attempts of subspeciation of *C. albicans* have been carried out, including various biotyping and chemotyping methods as well as susceptibility to 'killer factors' (Polonelli et al. 1985). Recent efforts are focused on typing of *C. albicans* isolates by restriction enzyme profiles, karyotyping, and other molecular biological techniques (see section on Genetics below).

The use of molecular technologies yielded new insights on the possible sexual mating of *C. albicans*, identifying a mating type-like locus (Hull and Johnson 1999; Hull et al. 2000; Magee and Magee 2000).

Candida dubliniensis

Phylogenetic trees have shown that *C. dubliniensis* is a discrete taxon within the *Candida* genus (Gutierrez et al. 2002). *C. dubliniensis* differs in its DNA fingerprint pattern from *C. albicans* (Sullivan et al. 1993, 1995). In addition, pulse field gel electrophoresis showed that *C. dubliniensis* has 10 or more chromosomes whereas *C. albicans* has seven to eight. *C. dubliniensis* differs by 2.3 percent from *C. albicans* in the V3 variable region of the large ribosomal RNA genes.

Candida glabrata

The taxonomic affiliation of this species is the most controversial among those described in this chapter as this yeast was classified in the genus *Torulopsis* (Kwon-Chung and Bennett 1992). The principal point of argument was whether the ability or inability to produce pseudohyphae/hyphae is a cogent reason to differentiate between two genera (*Candida* and *Torulopsis*) or not. This controversy was complicated by additional arguments on whether the name *Torulopsis* was validly published before *Candida* and the importance of keeping the two genera divided to avoid confusion among the mycologists (Odds 1988). It is currently generally accepted that this yeast should be assigned to the genus *Candida*.

Candida guilliermondii

Two varieties of *C. guilliermondii* have been described: *C. guilliermondii* var. *guilliermondii* and *C. guilliermondii* var. *membranaefaciens*. Both variants have teleomorphs: *Pichia guilliermondii* and *Pichia ohmeri*, respectively (Kurtzman 1998a).

Candida kefyr

C. kefyr is the anamorph of *Kluyveromyces marxianus*. *C. kefyr* was formerly designated as *Candida pseudotropicalis*, considerd to be the anamorph of *Kluyveromyces fragilis*. The two teleomorphs and their anamorphs were found to be conspecific (Kwon-Chung and Bennett 1992) and since *K. marxianus* and *C. kefyr* have precedence on *K. fragilis* and *C. pseudotropicalis*, respectively, they have been accepted.

Candida krusei

C. krusei is the anamorph of *Issatchenkia orientalis*. *C. krusei* differs from other pathogenic yeast species in a number of characteristics, such as its ability to grow on vitamin-free media (Odds 1988), the formation of flat, spreading colonies on Sabouraud's agar, cell wall mannan composition (Kogan et al. 1988), coenzyme Q numbers (Yamada and Kondo 1972) and other properties recently reviewed (Samaranayake and Samaranayake 1994).

Candida lusitaniae

C. lusitaniae is the anamorph of the ascomycetous yeast *Clavispora lusitaniae*. Genetic variability among clinical isolates was described (Merz et al. 1992). The involvement of *C. lusitaniae* as an opportunistic pathogen in humans was initially reported by Holzschu et al. (1979).

Candida parapsilosis

Nakase et al. (1979) showed that *C. parapsilosis* isolates could be divided into form I (arabinose positive) and form II (arabinose negative). The latter was shown subsequently to consist of anascosporogenous strains of *Loderomyces elongisporus* (Hamajima et al. 1987).

Candida tropicalis

The synonymy between *C. tropicalis* and *C. paratropicalis* has been confirmed by molecular biological methods (Wickes et al. 1992).

MYCOLOGICAL CHARACTERISTICS

Morphology

With a few exceptions (described below), macroscopic and microscopic cultural characteristics of the yeasts dealt with in this chapter are not specific enough to be a

basis for differentiation. Colonies cultured on glucose peptone agar (GPA), incubated at 25°C for 3 days, have a diameter of 2–3 mm, are white to cream colored, smooth or umbonate, and may become wrinkled after further incubation, as well as dull to glistening. Intraspecific variability of these characteristics is significant enough to preclude their use as criteria for species identification. In spite of the basic morphological similarity between various *Candida* spp., a number of characteristics, which are species specific, are evident on certain media, such as corn meal agar (CMA).

CANDIDA ALBICANS

On CMA, after 3 days of incubation, *C. albicans* will produce true- and pseudomycelium, grape-like groups of blastospores clustered at the septa and, typically for this species, at the end of the hyphae or short lateral branches, chlamydospores.

When incubated for 2 hours in 10 percent serum at 37°C, typical cell elongations – germ tubes – are formed. They differ from other, similar outgrowths produced by several other species by the absence of a constriction at the tube's base.

An interesting phenomenon is the 'phenotypic switching' described initially by Slutsky et al. (1985). It was demonstrated that strains of *C. albicans* possess the ability to undergo phenotypic switching expressed in colony morphology variations, such as white–opaque (Slutsky et al. 1987), traits associated with virulence (see section on Virulence factors below). This phenomenon was extensively investigated, including various genetic aspects (Soll 2002).

CANDIDA DUBLINIENSIS

C. dubliniensis is morphologically very similar to *C. albicans*. The main similarities are germ tube and chlamydospore production, while the main differences are the color produced when grown on ChromAgar medium and it does not grow well, or not at all, at 45°C (Gutierrez et al. 2002). Additional, subtler differences may be noted (Al-Mosaid et al. 2001).

CANDIDA GLABRATA

A characteristic of this species is the absence of hyphae or pseudohyphae on CMA.

CANDIDA GUILLIERMONDII (ANAMORPH) AND *PICHIA GUILLIERMONDII* (TELEOMORPH)

On CMA, formation of pseudohyphae may vary according to the strain from abundant to sparse. Blastospores may develop in small chains or in clusters. True hyphae are not produced.

P. guilliermondii is heterothallic. On 5 percent malt extract agar, asci containing one to four hat-shaped ascospores, which are liberated shortly after their generation, are formed. The majority of *C. guilliermondii* natural isolates, however, do not produce the teleomorph (Kurtzman 1998a).

CANDIDA KEFYR (ANAMORPH) AND *KLUYVEROMYCES MARXIANUS* (TELEOMORPH)

Colonies of this species, cultured on GPA and incubated for 3 days at 25°C, are relatively small: 1–2 mm. On CMA, in addition to pseudohyphae, blastospores may be observed. Occasionally the blastospores may be elongated and reach a length of up to 16 μm, a characteristic they share with *C. krusei*.

Kluyveromyces ascii contain one to four reniform ascospores, which tend to agglutinate after their release (Lachance 1998).

CANDIDA KRUSEI (ANAMORPH) AND *ISSATCHENKIA ORIENTALIS* (TELEOMORPH)

Colonies of *C. krusei* cultured on GPA become flat-topped after 5–7 days of incubation. Most blastospores are elongated and may reach 25 μm in length after a week. In Sabouraud's broth, *C. krusei* grows on top of the medium as a thick pellicle that may be observed after 2–3 days' incubation at 25°C (Figure 1).

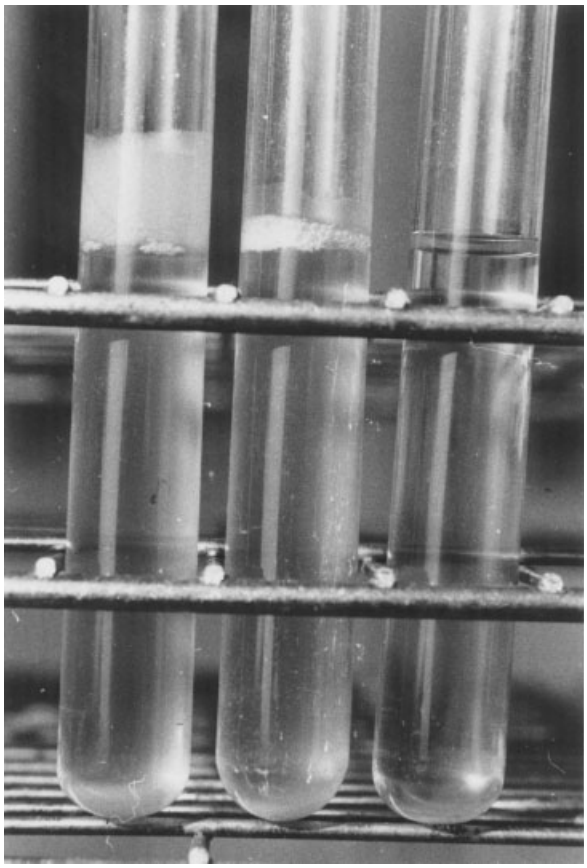

Figure 1 C. krusei, C. tropicalis, *and* C. albicans, *in Sabouraud's dextrose broth. Note the large pellicle of* C. krusei *(left) and small pellicle of* C. tropicalis *(center).*

Issatchenkia orientalis The taxonomic connection between *I. orientalis* and *C. krusei* has been confirmed only by comparison of genetic material (Wickes et al. 1992). Asci of *I. orientalis* contain one, occasionally two, smooth, spherical ascospores (Kurtzman 1998b).

CANDIDA LUSITANIAE (ANAMORPH) AND *CLAVISPORA LUSITANIAE* (TELEOMORPH)

On CMA, blastospores in verticillate chains are born on branching, often curved, pseudohyphae.

Clavispora lusitaniae is heterothallic. One to four ascospores, sometimes containing an oil droplet, are contained in each ascus. The ascospores are clavate (hence the name *Clavispora*), a characteristic unique to the genus. The spores might be slightly echinulate, a characteristic sometimes seen only by electron microscope (EM) examination. The type strain of *C. obtusa* (CBS 1944), which unlike *C. lusitaniae* does not assimilate lactate or ferment galactose, produced *Cl. lusitaniae* teleomorphs when mated with α mating types of *C. lusitaniae* (Rodriguez de Miranda 1979).

CANDIDA PARAPSILOSIS

On CMA, after 3 days incubation, long, regularly branching pseudohyphae with a 'pine forest' aspect are formed. Production of pseudomycelium may be, however, slight in some strains.

CANDIDA TROPICALIS

C. tropicalis grows on the surface of Sabouraud's dextrose broth as a thin pellicle which becomes evident after 2 days of incubation at 25°C (Figure 1).

Physiology

Candida spp. metabolize glucose via the hexose monophosphate pathway under aerobic conditions (assimilation), or via the Embden–Meyerhof pathway in anaerobiosis (fermentation). Additional metabolic mechanisms such as mitochondrial oxidative phosphorylation and the Krebs cycle and protein synthesis by 80S ribosomes (composed by a 60S and a 38S subunit) do not differ from those described in other eukaryotic cells (Braude 1986).

The enzymatic apparatus of *Candida* spp. is complex and has been extensively researched and reviewed (Odds 1988). The practical importance of *Candida* enzymes is significant since a number of them, such as proteases and those involved in sterol synthesis, may be directly involved in pathogenesis, or serve as target for antimycotic drugs, respectively.

Among catabolites secreted by some *Candida* spp. are acids, fatty acids, and alcohols, including ethanol.

Growth temperature seems to have an important influence upon morphogenesis of several *Candida* spp. While temperatures around 25°C promote primarily the formation of chlamydospores in *C. albicans*, higher temperatures, such as those present in potential hosts (around 37°C but sometimes reaching 43°C), will promote the formation of pseudohyphae (Braude 1986). Not all *Candida* spp. are able to grow at 37°C and higher temperatures, and consequently such capabilities are considered important pathogenic factors that separate potentially pathogenic strains from environmental saprophytes.

Genetics

A significant amount of data regarding the genomes, including genome size, number of chromosomes, and allocation of genes to specific chromosomes, of medically important *Candida* spp. has been accumulated during the last decade as recently summarized by Magee and Chibana (2002). Since *C. albicans* was studied more intensively than other species, this section focuses primarily on this microorganism. A significant recent development in *Candida* genetics is the *Candida albicans* Genome Project, targeted at the recognition of the fungus' genes (www-sequence.stanford.edu/group/candida).

The medically important *Candida* species have been traditionally assigned to the Deuteromycetes as only an anamorph state was known. Over the years, however, an ascomycetous teleomorph state was discovered for a number of *Candida* species (see section on Taxonomic comments below). *C. albicans* was considered as a species with no recognized sexual state. However, recent studies indicated that mating might occur in this species as well (Hull and Johnson 1999; Hull et al. 2000; Magee and Magee 2000). The *Candida* spp. dealt with in this chapter are considered diploid, except for *C. glabrata* (Doi et al. 1992; Kitada et al. 1995). Classical genetic studies, particularly those of *C. albicans*, were hampered due to its diploid nature and the lack of sexual reproduction. Nevertheless, molecular-genetic techniques enabled investigators to carry out studies revealing significant information regarding the genetics of *C. albicans*, and, to some extent, of other *Candida* spp. as well.

The principal findings related to *C. albicans* regarding the number of chromosomes, isolation of various mutations including site-directed mutagenesis, identification and sequencing of various genes, as well as allocation of part of them to specific chromosomes, DNA amplification, genetic cloning and gene expression are as follows.

The DNA content of *C. albicans* (nuclear and mitochondrial) was estimated to be in the range of 40 pg/cell (Riggsby et al. 1982). As cytological methods for demonstration of chromosomes are difficult, most karyotyping studies are based on electrophoretic methods (Magee and Magee 1987).

An important characteristic of *C. albicans* and other *Candida* spp. is the electrophoretic karyotype variability, which led to inconsistent results regarding the number of chromosomes (Magee and Magee 1987; Magee et al.

1988; Lasker et al. 1989; Wickes et al. 1991; Altboum 1994). The current notion is that *C. albicans* has eight pairs of chromosomes (Chibana et al. 2000). A physical mapping of chromosome 7 has been reported by Chibana et al. (1998).

Various types of mutants of *C. albicans* have been isolated spontaneously or following treatment with chemical or physical mutagens (Kirsch et al. 1990; Altboum 1994). These include auxotrophic strains, strains resistant to various substances, or temperature-sensitive and respiratory-deficient mutants expressed as 'petite' phenotype (Figure 2). The most frequently induced mutations were in genes involved in the biosynthesis of amino acids and nucleic acids expressed phenotypically by auxotrophic strains. Various techniques, including the widely applied method of complementation of homologous mutations in *Saccharomyces cerevisiae* (Malathi et al. 1994; Rosenbluh et al. 1985) have been used to isolate *C. albicans* genes from genomic libraries. This led to the isolation of a significant number of genes, some of which have been sequenced and/or located on chromosomes (Magee et al. 1988; Lasker et al. 1989; Rustchenko-Bulgac et al. 1990). Isolation of defined mutants and the corresponding genes led to development of transformation methods that resulted in gene expression. An important development in the area of mutagenesis was the introduction by Fonzi and Irwin (1993) of the targeted mutagenesis method, allowing the isolation and identification of specific mutants and the corresponding genes.

Genetic-molecular studies of other species besides *C. albicans* focused primarily on karyotyping (Asakura et al. 1991; Lott et al. 1993; Doi et al. 1994) or use of molecular techniques for epidemiological typing (Carruba et al. 1991; Doebbeling et al. 1991, 1993; Branchini et al. 1994) or phylogeny (Hendriks et al. 1991; Kurtzman 1993). Isolation of mutants (Gleeson et al. 1990) and transformation in *C. tropicalis* (Sanglard and Fiechter 1992), as well as isolation and sequencing of the *SAP* gene (Togni et al. 1991; Ganesan et al. 1991) in this species have been reported. In addition, cloning of genes encoding for acid proteases in *C. parapsilosis* (de Viragh et al. 1993) and genetic manipulation in *C. glabrata* (Zhou et al. 1994) have also been reported. Furthermore, efforts have been focused on use of molecular methods, primarily polymerase chain reaction (PCR), for diagnostic purposes attempting identification and detection of various species (Lehmann et al. 1992; Burgener Kairuz et al. 1994; Maiwald et al. 1994).

ECOLOGY AND EPIDEMIOLOGY

Candida spp. are currently considered the fourth most common cause of hospital acquired systemic infections in North America, accounting for 10 percent of all bloodstream infections (Richardson and Warnock 1997; Sullivan and Coleman 2002), and which may lead to mortality rates of up to 35 percent (Wenzel 1995). Although most *Candida* spp. have been isolated from animal and other environmental sources (Mok et al. 1984; Mok and de Carvalho 1985; de Hoog et al. 2000), human infections are usually endogenous. *Candida* spp. can be isolated from various sites on or in the human body of 30–50 percent of asymptomatic individuals (Richardson and Warnock 1997), primarily the gastrointestinal (GI) tract, the oropharynx, the vagina, and the skin (Mok and da Silva 1984; de Hoog et al. 2000). Variations regarding the presence of *Candida* spp. in healthy individuals may be a function of various factors such as climate, age, or diet of the surveyed population. As summarized by Odds (1988), the range of *Candida* isolations from the oral cavity is 1.9–41.4 percent, the GI tract 0–55 percent and the vagina 2.2–68 percent. The same source (Odds 1988) indicates that mean values of data from a number of epidemiologic surveys reveal that *C. tropicalis* and *C. glabrata* are the second most frequent species isolated, from the oropharynx in the case of the former, and from the vagina and the GI tract the latter.

C. albicans is generally considered the major pathogen among the *Candida* species. Although an increase in the prevalence of non-*albicans* species has been noted during the last decade (Hazen 1995; Krcmery and Barnes 2002; Nguyen et al. 1996) it is still usually the most frequently isolated species (Edmond et al. 1999; Pfaller and Diekema 2002), albeit the differences have become less substantial. Recent surveys indicate (Krcmery and Barnes 2002; Pfaller 2003) that besides *C. albicans*, the four most common *Candida* spp. isolated from candidemia patients include *C. parapsilosis*, *C. tropicalis*, *C. glabrata*, and *C. krusei*. About a dozen more rarely isolated additional non-*albicans* *Candida* spp., such as *C. guillermondii*, *C. kefyr* or *C. lusitaniae*, have been reported as causes of candidiasis (Krcmery and Barnes 2002; Pfaller and Diekema 2002). Particu-

larly noteworthy is the identification of a novel *Candida* species – *C. dubliniensis* – as a pathogen (see section on *Candida dubliniensis* below).

Analogy between two isolates based primarily on phenotypic morphological and physiological characteristics is often insufficient. Therefore, efforts have been made during recent years to apply molecular biological techniques (Pfaller 1992b; Sullivan and Coleman 2002), such as pulsed-field gel electrophoresis (Pfaller et al. 1998), randomly amplified polymorphic DNA analysis (Lehmann et al. 1992; Lin and Lehmann 1995; Holmberg and Feroze 1996), and restriction fragment length polymorphism (Joly et al. 1996, 1999; Lockhart et al. 1997), to epidemiological studies of various *Candida* spp. This approach is exemplified in a recent study of Singh et al. (2002), who by using contour-clamped homogenous electrical field analysis in a survey on vaginitis caused by *C. krusei*, identified two genotypes (Singh et al. 2002).

It is generally accepted that the incidence of yeast infections has increased during the last decades (Pfaller and Wenzel 1992). Several reasons have been mentioned as predisposing to this increase, such as immunosuppression (pathological and iatrogenic) and increase in the use of broad-spectrum antibacterials, to mention but two. However, other factors, such as higher awareness and, more importantly, improved and easily accessible diagnostic tools, may have contributed significantly to the observed epidemiologic changes.

In addition to the overall increase of *Candida* infections, epidemiologic shifts in the relative prevalence of the different *Candida* spp. and emergence of new pathogens has occurred (Hazen 1995; Pfaller and Diekema 2002). Among the possible factors contributing to these shifts, an important role has been attributed to antifungal drugs. It is believed that the introduction of various antimycotic agents into extensive use has resulted in the selection of specific species that are inherently less susceptible to the specific drug (most known examples are *C. glabrata* and *C. krusei* exhibiting resistance to fluconazole). In addition, more recently, other factors, such as demographic parameters or even specific genetic susceptibility, have been suggested as contributing to the change in the relative proportions of the different *Candida* spp. involved in human pathology (Pfaller 2003).

In view of the scope of this chapter, the following sections deal only briefly with epidemiologic aspects of the major pathogenic *Candida* spp., and the reader interested in more detailed information is referred to specific literature.

Candida albicans

C. albicans is isolated more rarely than other *Candida* spp. from environmental sources. This might be a result of this species' relatively high adaptation to a parasitic way of life and consequent loss of some of the capacities possessed by other species. Two serotypes have been recognized: serotype A is more prevalent than serotype B among clinical isolates (Auger et al. 1979). Studies with *C. albicans* isolated from immunosuppressed patients (Brawner et al. 1992) indicated a higher incidence of serotype B. These finding may, however, differ according to the geographical area. Interestingly, a correlation between susceptibility to flucytosine and serotype has been noted: while serotype A isolates are susceptible, serotype B isolates often exhibit resistance (Auger et al. 1979).

Outbreaks of *Candida* infections traced back to hospital personnel or contaminated materials, in risk populations such as neonates (Shian et al. 1993; el-Mohandes et al. 1994) or coronary bypass patients (Isenberg and Tucci 1989) have been reported.

Candida dubliniensis

The initial isolation of *C. dubliniensis* was from the oral cavity (Sullivan et al. 1995) and subsequently from other sites including vagina (Coleman et al. 1997), urine (Polacheck et al. 2000), and blood (Meis et al. 1999). Although the original isolates were from HIV-positive patients, later this yeast was cultured from non-HIV carriers receiving chemotherapy, following bone marrow transplantation (Meis et al. 1999), or broad-spectrum antibacterial treatment (Polacheck et al. 2000). It was also reported recently by Jabra-Rizk et al. (2001) that *C. dubliniensis* was isolated from healthy children.

It is interesting that *C. dubliniensis* may develop resistance to fluconazole and this may possibly have contributed to the emergence of this species in HIV carriers/AIDS patients (Sullivan et al. 1999).

Candida guilliermondii

C. guilliermondii has been isolated from various environmental sources such as swimming pools (Aho and Hirn 1981), soil, sand, and seawater (Boiron et al. 1983), as well as amphibians (Mok and de Carvalho 1985), wild and domestic birds (Mangiarotti et al. 1993), and mammals, including the human cutaneous surface. In addition, *C. guilliermondii* has been isolated from the hands of hospital personnel (Strausbaugh et al. 1994). In another report of nosocomial infections caused by this yeast in a neonatal intensive care unit, the source of infection was the heparin solution used to flush 'butterfly needles' used for blood sampling (Yagupsky et al. 1991).

Candida glabrata

This species is one of the most prevalent among those isolated from the oral cavity (Stenderup 1990) or vagina of healthy individuals (Odds 1988). The prevalence of

this species among those causing human disease has increased significantly (Borg von-Zepelin et al. 1999; Pfaller and Diekema 2002), becoming an important cause of candidemia. In addition, it is a major pathogen involved in candidal vaginitis (Sobel 1998) or denture stomatitis (Cumming et al. 1990). It is generally believed that increased prevalence of this species as a pathogen is due to selective pressure resulting from its resistance to fluconazole (Richardson and Warnock 1997). In addition, it has been recently suggested that other factors, such as age or geographical area, may also play a role (Pfaller 2003).

Candida kefyr

This species has been involved only rarely in human pathology. Several cases of disseminated yeast infections caused by *C. kefyr* have been described and this species was isolated sporadically from vaginal, urinary, ear, and GI infections (Davis 1986).

Candida krusei

C. krusei has been isolated from various environmental sources (Do Carmo Sousa 1969) but only rarely from the mucosal surfaces of healthy carriers (Odds 1988). The involvement of *C. krusei* in pathological processes has increased in the last few years and may continue to do so, considering its resistance to fluconazole, widely used as an antimycotic prophylactic drug. In fact, a comparison between the incidence of disseminated *C. krusei* in 1989 and 1990, the year in which fluconazole prophylaxis was introduced, showed that the latter practice led to an increase of such cases while no such change was observed for *C. albicans* and *C. tropicalis* cases (Wingard et al. 1991). Indeed, *C. krusei* became an important cause of difficult to treat cases of candidemia (Pfaller 2003). Among mucocutaneous *Candida* infections it is an important cause of vaginitis (Singh et al. 2002).

Candida parapsilosis

C. parapsilosis has a wide distribution in nature and has been found to be part of the normal human skin flora especially subungual spaces (Weems 1992).

C. parapsilosis has been reported as a contaminant of high concentration glucose solutions and prosthetic material (Branchini et al. 1994). A number of nosocomial infections with this yeast species have been reported. It was isolated from cases of sepsis in an intensive care nursery (Shian et al. 1993; el-Mohandes et al. 1994), it was reported to be prevalent in patients with indwelling devices or those fed parenterally (Herrero et al. 1992; Martino et al. 1993; Krcmery and Barnes 2002), possibly as a result of its tendency to form biofilms on catheter tips (Kuhn et al. 2002). Nosocomial infections were connected with the presence of *C. parapsilosis* on hospital equipment, personnel hands, and pigeon guano on window sills (Greaves et al. 1992; Oie and Kamiya 1992; Sanchez et al. 1993), and infection of high-risk patients connected with such contamination (Greaves et al. 1992; Sanchez et al. 1993). Cases of endophtalmitis caused by *C. parapsilosis* following lens implants has been reported (Kauffman et al. 1993).

Candida tropicalis

Odds (1988) reports that according to some surveys, *C. tropicalis* is a relatively prevalent pathogenic yeast species in the oral cavity of asymptomatic carriers. *C. tropicalis* has been shown to be involved in various human pathologies such as fungemia (Pfaller 2003) post-surgery infections, osteomyelitis (Ferra et al. 1994), endocarditis (Shmuely et al. 1997; Gerritsen et al. 1998). In addition to endogenous infections, which are the most common, cases of fungemia in a neonatal intensive care unit have been connected to the presence of the fungus on the hands of personnel (Finkelstein et al. 1993).

Candida lusitaniae

C. lusitaniae was first described as part of the normal microbial flora of warm-blooded animals by van Uden and do Carmo-Sousa (Sanchez et al. 1992). *C. lusitaniae* has been isolated from various animal sources (pigs, mastitis milk, bird droppings), alimentary products (citrus peel juice), and clinical specimens (sputum, feces, urine) (Merz 1984).

The prevalence of *C. lusitaniae* among yeast species isolated from clinical cases is relatively low. During a 15-month study, only 0.64 percent of the isolated yeast species were identified as *C. lusitaniae* (Merz 1984). Nosocomial colonization of the digestive or urinary tracts has been reported and the possibility of transmission by hands of hospital personnel suggested (Sanchez et al. 1992; Strausbaugh et al. 1994). Restriction enzyme analysis of *C. lusitaniae* isolates cultured in the same study showed that although most patients carry the same strain throughout the period of colonization, occasionally, two different strains may be present in different body sites (Sanchez et al. 1992).

The distribution of the two mating types of *Cl. lusitaniae* is unequal: a ratio of 1:6 between the 'a' and the 'α' mating types has been reported.

PATHOGENICITY AND PATHOGENESIS

Virulence factors

In addition to previously available information regarding virulence properties of *Candida* spp. (Cutler 1991; Odds 1994; Segal 1994b), newer studies with this subject have

been summarized in several review articles in recent literature (Staib et al. 2000; Calderone and Fonzi 2001; Haynes 2001; Navarro-Garcia et al. 2001; Soll 2002). While many of the reviews describe investigations concentrating on specific virulence attributes, such as adherence to host tissues (Cotter and Kavanagh 2000; Sundstrom 2002), proteinases (De Bernardis et al, 2001; Monod and Borg-von Zepelin 2002), phospholipases (Ghannoum 2000), or biofilm formation (Waldvogel and Bisno 2000; Ramage et al. 2001), the most intriguing facet of the recent studies is the focus on isolation and/or expression of specific virulence genes (Staib et al. 2000; Hoyer 2001; Navarro-Garcia et al. 2001). Although the majority of these reviews report on research involving *C. albicans*, studies on additional *Candida* spp., such as *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, or *C. dubliniensis* have also been reviewed (Haynes 2001; Gutierrez et al. 2002).

The virulence traits of *Candida* spp., particularly of the major pathogen, *C. albicans*, to which possible roles in pathogenesis of candidiasis have been attributed, are believed to be associated primarily, with:

- the ability of the fungus to bind (attach, adhere) to host tissue as an initial step in the recognition and interaction with the host. Special attention has been given more recently to an associated phenomenon – biofilm formation, as a significant factor in the pathogenesis of candidiasis, affecting adversely the host's response to infection and causing difficulties in therapy
- the production of specific enzymes that could facilitate tissue penetration and invasion, such as secretory aspartyl proteinases (SAPs) and phospholipases
- yeast–hyphal morphogenetic transformation, which could also facilitate penetration and, in addition, assist the microbe to evade the host's defense system
- phenotypic switching
- various immunomodulatory effects of fungal determinants, which could contribute to reduced activity of the host's defense system.

Although the above-mentioned mechanisms of virulence are supported by evidence provided by various experimental studies and epidemiologic–clinical observations, it should be emphasized that assessment of microbial virulence under actual in vivo conditions is a complex issue, since virulence involves a combination of traits, while in experimental systems a single characteristic is assessed under given conditions.

The ability of *Candida* to attach to host tissues has been extensively studied both in vitro and in vivo, the latter mostly in experimental animal models, and reviewed in several articles (Segal 1987a, 1994b; Calderone and Braun 1991; Kennedy et al. 1992; Segal and Sandovsky-Losica 1995, 1997). As stated above, the more recent studies and reviews summarizing those studies (Cotter and Kavanagh 2000; Sundstrom 2002) concentrate on genetic aspects related to adhesion or association with the host (Hoyer 2001). As it is outside the scope of the present text to exhaust in detail the subject, only the principles and the major conclusions drawn from the various studies are detailed.

In vitro systems showed that *Candida* can adhere to a variety of substrates, such as exfoliated human epithelial cells (buccal, vaginal, dermal) (Segal and Sandovsky-Losica 1995), human tissue lines (endothelial, Hela) (Hostetter 1994a, b) animal tissue segments (oral, gastrointestinal) (Segal and Sandovsky-Losica 1995) or inert surfaces (various polymers used for indwelling medical devices) (Waldvogel and Bisno 2000). These experiments revealed that a gradient in the level of adherence could be noted, which correlates with the pathogenicity of the *Candida* spp. in man and animals. Thus, *C. albicans* was, generally, the most adherent *Candida* species. However, intraspecies variation expressed by different adhesion ability of various isolates of the species was also noted (Samaranayake et al. 1994). In addition, it was shown that mutants with reduced adherence exhibited also decreased pathogenicity in vivo (Roth-Ben Arie et al. 2001). Adhesion to tissues was found to be dependent on various environmental conditions affecting the fungus, and influenced by various host factors, such as fungal surface hydrophobicity, growth medium, and growth conditions, or hormonal and immune status of the host, respectively (Kennedy 1988).

Animal experimental models and ex vivo systems have confirmed many of the data derived from the in vitro systems. They showed that the attachment of the fungus to the host's tissues initiates colonization and the infectious process. This concept was the basis for attempts to prevent development of infection by intercepting the binding of the fungus to host's tissues (Segal and Sandovsky-Losica 1997). Such an approach could be considered as a novel prophylaxis modality for prevention of disease.

Studies aimed at identifying the fungal surface molecules involved in the binding process led to the recognition of several putative adhesins: mannan (Calderone and Braun 1991), the mannoproteins – primarily their proteinous moiety (Douglas 1987) – and chitin (Segal and Sandovsky-Losica 1995, 1997). Miyakawa et al. (1992) suggested that antigen 6 of the mannan might be associated with adhesin activity. Different adhesins may, possibly, exist on different *Candida* species (Bendel and Hostetter 1993). The counterpart receptor molecule on the host cell is, depending on the type of cell, apparently, fucosyl, glucosamine, fibronectin or arginine-glycine-asparagine (RGD) (Hostetter 1994a, b).

More recent studies reported several additional adhesins in *C. albicans*, such as Alsp and Hwp1p. Hoyer's group described a family of surface glycoproteins, the Alsp (Hoyer 2001), that is involved in fungal binding and may act as adhesins, thus being considered virulence attributes, playing a role in pathogenesis. It was also

found that at least nine genes encode these molecules. Another probable adhesin, a cell wall protein as well, the Hwp1p, was described (Staab and Sundstrom 1998; Tsuchimori et al. 2002). It was shown in these studies that mutants deficient in these adhesins were less virulent. Gale et al. (1998) have demonstrated the linkage of adhesion, hyphal growth, and virulence of *C. albicans* to the *INT1* gene. Int1p, the integrin-like protein, is considered a *C. albicans* virulence factor (Hostetter 2000).

Regarding other *Candida* spp., Epa1p, a cell wall protein acting as an adhesin in *C. glabrata*, was reported (Cormack et al. 1999). *ALS* genes have been reported for *C. tropicalis* and *C. dubliniensis* (Hoyer et al. 2001).

C. albicans also possesses surface components (e.g. iC3b), which are associated with binding to fibrinogen and complement (Calderone and Braun 1991). This interaction and speculated molecular mimicry mechanisms of mammalian integrins by *C. albicans* surface proteins (Hostetter 1994a) may affect the binding to neutrophils and thereby phagocytosis, which in turn will affect the host's defense system, and should thus be considered as additional factors playing a role in the pathogenesis of candidiasis.

As sequelae of attachment, microorganisms can grow in colonial communities and produce the so-called 'biofilms,' instead of single entities – the 'planktonic forms.' Biofilm production was shown for *Candida* spp. (Kumamoto 2002), particularly for *C. albicans* (Chandra et al. 2001). The biofilms contain extracellular materials (ECM), composed of proteins, carbohydrates, and other substances (Baillie and Douglas 2000). Other significant characteristics of biofilms are the poorer response of the pathogen in the biofilm to antimicrobials (Ramage et al. 2002) and the difficulties of the hosts' defense systems to cope with the microbe, resulting in difficulties of eradication of infection. *Candida* biofilm formation has important clinical ramifications, as biofilms are formed on inert surfaces of medical devices (Sanchez-Sousa et al. 2001), such as catheters, artificial dentures, prosthetic valves, the use of which is known to be associated with increased risk for development of systemic infections.

The factors involved in fungal tissue penetration and invasion, which may follow the initial step of interaction between the fungus and host cell, are related to the morphogenetic change from yeast to hyphae, and to production of hydrolytic enzymes (Odds 1994). Among the latter, the SAPs (Ruchel et al. 1992) and phospholipases (Ogawa et al. 1992) seem to be the major enzymes playing a significant role in pathogenesis of candidiasis (Ghannoum 2000; Hube 2000).

SAPs can be found following adhesion of *C. albicans* to epithelial cells. As in the case of adhesion, SAP production was exhibited, primarily, by pathogenic *Candida* spp. Specifically, while enzyme activity was revealed by *C. albicans*, *C. tropicalis*, and *C. parapsilosis* (Sono et al. 1992; Fusek et al. 1994) other *Candida* spp. exhibit it only partially. Enzymes were detected in vivo during infection (Ruchel et al. 1991) and in association with phagocytosis (Borg and Ruchel 1990). SAP-deficient mutants were less pathogenic in inducing experimental infection and unable to invade tissue (Kwon-Chung et al. 1985; Ross et al. 1990). It is believed that SAP production may facilitate invasion through degradation of keratin and collagen.

Currently, the SAP family consists of nine enzymes, for which genes have been isolated (Hube and Naglik 2001), and for which correlations with specific clinical forms have been described. Thus, *SAP2* has been associated with vaginal candidiasis, while other SAPs (e.g. *SAP1–SAP6*) have been associated with systemic infection (Hube et al. 1997; Sanglard et al. 1997). A most recent review by Monod and Borg-von Zepelin (2002) states that 10 genes of *C. albicans* SAPs have been cloned thus far. Of interest are the studies in AIDS patients undergoing antiretroviral treatment with inhibitors of aspartic proteinases, that revealed a decrease in incidence of oropharyngeal candidiasis in these patients (Egger et al. 1997), possibly due to inhibition of production of Sap protein, involved in the fungal adherence to the mucosal surface (Borg-von Zepelin et al. 1999).

Phospholipases have been shown to be fungal virulence factors (Ghannoum 2000; Hube 2000; Monod and Borg-von Zepelin 2002; Sundstrom 2002). Phospholipases have been shown for *C. albicans* and other *Candida* spp., such as *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, or *C. krusei* (Ghannoum 2000). As in the case of the SAP enzymes, a role in the adherence of *Candida* to host cells and tissue penetration has been attributed to phospholipase production (Ghannoum 2000). Two genes encoding phospholipases in *C. albicans* have been cloned (Leidich et al. 1998; Sugiyama et al. 1999) and disruption of the genes affected the fungal virulence (Leidich et al. 1998). It is interesting in this context to mention the study of Hube and colleagues (Hube 2000) reporting on ten genes encoding lipases that, the authors suggest, may have a role in the microorganism's virulence.

The importance of the transition to the hyphal form as a virulence factor, recognized for many years, has been corroborated more recently by molecular studies (Madhani and Fink 1998). The transformation into the hyphal form is noted during active infection (Odds 1988; Edwards 2000). It is believed that phospholipases concentrated at the hyphal tip may be related to the greater invasiveness of this form as compared to the yeast. In addition, the hyphae, being larger than the yeast form, are more resistant to phagocytosis (Diamond and Krzesicki 1978), and thus the morphological change contributes to increased pathogenic potential of the fungus. An interesting recent observation reported by Sundstrom (2002) indicates the presence of the adhesin Hwp1 only on the surfaces of germ tubes and mature hyphae, and not on that of the other morphological

forms of *C. albicans*. Furthermore, it was also shown by the same group of investigators (Sundstrom et al. 2002) that this cell wall component contributed to the yeast's virulence in murine oropharyngeal candidiasis. Recent molecular studies on *C. albicans* dimorphism (Liu 2001) revealed the association between specific genes involved in the morphological transition to hyphae and the fungus' virulence. A *Candida CLA4* mutant, with reduced yeast to hyphae transition ability, was found to have a lower virulence in mice (Madhani and Fink 1998). Cyclic AMP has been shown to be involved in blastospore-hypha transition; thus the cAMP signaling pathway plays a role in pathogenesis (Bahn and Sundstrom 2001).

Phenotypic switching associated with morphological colony changes from smooth to rough or fuzzy type, white to opaque, and other morphological changes is a phenomenon described first in the 1980s (Slutsky et al. 1985, 1987). Later studies associated phenotypic switching with differences in antigenicity (Anderson et al. 1990), pathogenic potential (Jones et al. 1994), and indicated genetic regulation (Perez-Martin et al. 1999). Phenotypic switching is considered as a potential virulence characteristic, as it may express the fungal plasticity, contributing to its adaptability to various anatomic sites of the human body and thereby possibly enabling the variety of clinical entities it causes, as well as play a role in the transition from commensalisms to pathogenicity (Soll 2002). Furthermore, phenotypic switching may assist the microbe to evade the host's defense systems, in analogy to the bacterial 'phase transition' phenomenon.

Several investigators (Cassone 1989; Domer and Garner 1989; Garner et al. 1990; Domer et al. 1992) described immunomodulatory activity of fungal surface components. An immunosuppressive effect of *C. albicans* in experimental models was noted, which was attributed particularly to manann (Domer 1989; Domer and Carrow 1989).

Should such a mechanism or a similar one occur in clinical situations, this could be added to the arsenal of candidal pathogenic traits contributing to the pathogenesis of the infection.

This section can be concluded by the belief that the current technology of transcript profiling using DNA arrays, which are already commercially available, may lead in the future to identification of additional virulence traits and, most importantly, possibly those expressed in vivo.

Pathogenesis of candidiasis

In discussing pathogenesis of candidiasis, it has to be kept in mind that *Candida* is a human commensal, so that the infectious source is mostly endogenous (Kennedy 1989). The GI tract is considered a major reservoir for candidiasis, e.g. in vaginitis or diaper rash. Moreover, from the GI tract the fungus can invade the bloodstream following damage to the GI mucosa, such as induced by anticancer treatment (irradiation or chemotherapy) (Cunningham et al. 1985) or major surgery, and spread hematogenously into various organs, causing deep-seated/disseminated infection. It is believed that *Candida* may also be able to cross the intact GI mucosa by a process termed 'persorption' (Krause et al. 1969) following fungal overgrowth, which can result from changes in the normal balance of the microbial flora due to extensive antibiotic treatment. Although previous experimental studies, such as those reported by Sandovsky-Losica et al. (1992), have already shown that systemic candidiasis originating from the GI tract follows adhesion to its mucosa (Sandovsky-Losica and Segal 1990; Sandovsky-Losica et al. 1992), more recent investigations have revealed additional aspects of this interaction. Wiesner et al. (2002), using enterocyte cultures, reported that the *INT1* gene was involved in adherence of *C. albicans* to enterocytes. Moreover, this involvement was more marked for blastospores than the hyphal form (Wiesner et al. 2002). However, *Candida* can be introduced from exogenous sources as well (Edwards 2000). These may include introduction through various catheters and lines, or other indwelling/prosthetic medical devices (Khatib and Clark 1995). This route is of particular importance in the development of deep-seated and systemic candidiasis as most of those therapeutic modalities are used primarily in compromised hosts whose defense systems are unable to combat the introduced pathogen. An interesting observation was made by Rangel Frausto et al. (1994) regarding nosocomial transmission of yeasts. The survival and transmission of *Candida* spp. on and by human volunteers has been assessed and it has been shown that, although the half-life of the microorganisms was relatively low, more than 10^3 colony-forming units of the yeast remained on the hands of the volunteers after 45 minutes (Rangel Frausto et al. 1994).

Once *Candida* entered the bloodstream, whether from exogenous or endogenous source, the microorganisms have to adhere to the endothelial surface of the blood vessels, before dissemination into tissues (Klotz 1992). This process involves endocytosis, endothelial invasion, and response to the invading pathogen expressed in production of proinflammatory cytokines, such as tumor necrosis factor-alpha (TNF-α) or interleukin (IL)-6 (Orozco et al. 2000). It was also noted that germ tubes are better endocytosed than blastospores (Phan et al. 2000).

It is noteworthy that proinflammatory cytokines have been shown recently to be involved in the pathogenesis of candidiasis (Brieland et al. 2001). In a model using immunocompetent mice, Brieland and colleagues compared the pathogenesis of intravenous (IV)-induced infection by *C. albicans* versus that of *C. glabrata*,

analyzing organ colonization and cytokine production. They found that while kidneys of *C. glabrata* infected animals were colonized, the animals nevertheless, survived, contrary to those infected by *C. albicans*, that were colonized as well and succumbed to the infection. The authors suggest that the difference is associated primarily with a more rapid induction of the proinflammatory cytokines in response to *C. glabrata* than to *C. albicans*.

Person-to-person transmission is not a predominant mechanism of pathogenesis in candidiasis, and is expressed primarily in oral thrush of newborns acquired during birth from their mothers affected by vaginal infection, or noted more rarely in sexual transmission from vaginitis patients to their male partners.

The normal innate mammalian defense system against *Candida* infection includes intact dermal surfaces, intact mucosa, unspecific humoral factors, and the immune system – humoral and cellular (Greenfield 1992; Levitz 1992).

The first line of defense, which protects, primarily, before the mucocutaneous forms of candidiasis, is the unbreached skin and mucosa (Edwards 2000). As detailed under the section on Clinical entities below, risk factors, which increase the susceptibility to these types of *Candida* infections, include maceration of skin, changes of microbial flora, trauma to skin/mucosa, hormonal changes affecting skin integrity or local defense and/or excess of carbohydrates on surfaces, as seen in diabetics. It is believed that the skin, in addition to its function as a barrier, possesses an inflammatory–immunological activity as well (Wagner and Sohnle 1995). The latter may involve the specific skin cells – epidermal Langerhans cells and keratinocytes – which may function as antigen-presenting cells, engage in phagocytosis or/and produce various cytokines. As indicated above, breaching the intactness of the skin (e.g. through intravenous catheters) or of the GI mucosa can lead also to introduction of the organism into the bloodstream, either from exogenous or endogenous (GI tract) sources, respectively. Thus, damage to the integuments may be considered as a risk factor for the development of systemic candidiasis. Additional nonspecific, nonimmune factors to which a possible role in defense has been attributed include iron-binding proteins, such as transferrin or lactoferrin (Nikawa et al. 1993).

The second line of defense, which comes into action following fungal penetration, includes phagocytic and candidacidal activity of polymorphonuclear (PMN) (primarily, neutrophils) and mononuclear (primarily, monocytes) cells (Marodi et al. 1991a, b; Greenfield 1992; Levitz 1992). These processes involve myeloperoxidase and superoxide production, or cationic proteins. PMN activity is of crucial significance in protection against the deep-seated forms of *Candida* infections, as can be judged by epidemiologic data that indicate that an increased rate of these infections is associated with neutropenia or defective PMNs (see sections on Clinical entities and Immunity below).

As to specific activity of the immune system, despite numerous experimental studies and clinical observations there is no clearcut concept of the activity of the various elements of the system and the mechanisms underlying that activity. T lymphocytes involved in cell-mediated immune response seem to be of significance, particularly in defense against mucocutaneous forms of candidiasis (Domer and Carrow 1989). Patients with T-cell deficiencies, such as AIDS patients, are especially prone to these infections. The role of these cells in resistance to systemic candidiasis is more controversial (see discussion in the section on Immunity below). Opsonizing antibodies (IgG) seem to contribute to phagocytosis and thereby to defense. An additional humoral element of the immune system involved in defense is, apparently, the complement cascade (Gelfand et al. 1978).

ANTIGENICITY, IMMUNE RESPONSE, AND IMMUNITY

The immune response of the mammalian host to *Candida* infection, the antigens eliciting this response, and the eventual resulting immunity, as well as the defense mechanisms involved in the process, constitute complex issues which have attracted extensive research over the years, research which has not always led to unequivocal conclusions. Nevertheless, certain pertinent generalizations can still be drawn.

Antigenicity

In discussing the topic of antigenicity, one should bear in mind that the definition of the term should be in the frame of a specific context; whether:

- in relation to antigens which elicit immune responses in general
- as antigens which elicit a response during infection, a response which can be measured and used as a diagnostic tool
- as antigens which confer resistance to the infection and may be considered 'protective antigens.' As in many microbial systems, the antigens eliciting a given response or having a protective role may be different.

In defining the antigenicity of *Candida*, primarily that of *C. albicans*, most studies, particularly earlier investigations, concentrated on the cell wall. Those studies indicated that the mannoprotein complex, particularly the polysaccharidic moiety of the *Candida* cell wall, is the major antigenic component. It was postulated that the backbone structure of the mannan confers the antigenic properties to the whole group, and the specific antigenicity of a given species or variety is apparently

due to the different side chains of the mannan molecule (Reiss 1986; Reiss et al. 1992). This hypothesis was the background of extensive experimental studies of Tsuchiya et al. (1965), and over the years of other investigators (Miyakawa et al. 1986) as well. These studies, using agglutination assays with anti-*Candida* sera, culminated in the development of an antigenic profile of *Candida* spp. of medical interest. The presence of heat-labile and heat-stable antigens, which could be common or specific to a particular species or several species, was shown. A commercial kit based on this principle enables us to differentiate among the most commonly encountered pathogenic *Candida* spp. Limited serotyping of *C. albicans* into two serotypes, serotype A and serotype B, as described by the studies of Hasenclever and Mitchell (1961), was also based on a similar principle. Summaries of studies conducted in the last decade on *Candida* spp. cell wall, such as that of Chauhan et al. (2002), contribute to a more detailed knowledge of its composition and molecular structure. It became evident that, besides the traditionally recognized polysaccharides, other components such as chitinase and glycolipids can be considered important cell wall constituents. Glycosylphosphatidylinositol (GPI) was found to play a role in anchoring proteins to the cell wall polymers (Fonzi 1999). In addition to cell wall composition and structure, studies were also aimed at characterizing cell wall antigens. Ponton described several types of antigens expressed either on the surface of germ tubes, blastoconidia, or both (Ponton et al. 1993, 2002). La Valle et al. (2000) studied the 65 kDa mannoprotein of *C. albicans* and found it to be a major immunodominant antigen. The group of Poulain concentrated on phospholipomannans (Poulain et al. 2002; Trinel et al. 2002). They showed that *C. albicans* can synthesize specific β-1,2-oligomannosides which have antigenic properties.

If antigens are to be used as reagents for diagnostic purposes, it is of importance to define the aim. If the aim is to differentiate between colonization of superficial mucocutaneous surfaces and deep-seated organ involvement, it would seem reasonable not to employ *Candida* cell wall antigens. Since *Candida* is an ubiquitous microorganism and human commensal, it elicits immune responses in the host to the fungal cell wall to which there is constant exposure. On the other hand, a reasonable approach would be to search for antigens of the *Candida* cytosol, which are released during infection and elicit a measurable immune response. This rationale was the basis for development of immunodiagnostic tests in which the reagent was a cytoplasmic *Candida* extract, standardized by its protein content (Reiss et al. 2002). More defined antigens, mostly of proteinaceous nature, to which the above-mentioned characteristics have been attributed, have also been suggested. These include the enolase, a protein with catabolic enzymatic activity (Franklin et al. 1990); a 47–48 kDa protein described by Matthews et al. (1988), who believe that it has some protective role in AIDS patients and which could be identical with the enolase, and more recently La Valle et al. (1995) described a 70–80 kDa heat shock protein (HSP) with immunogenic activity, and which the authors suggest as a possible reagent in diagnosis. Undefined nonprotein antigens, probably a glycoprotein, and the polysaccharide mannan, have been believed to be released during systemic *Candida* infections and consequently tests aimed at the detection of these antigens for diagnostic purposes were devised (the Ramco and Pastorex kits, respectively).

It should be noted that some of the antigens mentioned above, such as the 65 kDa protein or the oligomannosides, may be considered as potential reagents with diagnostic value as well (La Valle et al. 2000; Sendid et al. 2002).

The identification of antigens, the response to which would induce protection to the infection, is a subject even more complicated and controversial than the identification of antigens of diagnostic relevance. This is so despite experimental attempts, as mentioned later, to induce protection against experimental infection by immunization with various *Candida* preparations. These have included whole live organisms, live-attenuated *Candida* cells and those killed by different methods or noncellular preparations (Segal 1987b, 1991). Among the latter can be included antigens prepared by the author with *Candida* ribosomal fractions, which induced, in animal models, significant protection against systemic candidiasis (Segal 1989). The protection is, apparently, due primarily to the ribosomal-protein(s) moiety. Interestingly, specific ribosomal proteins, the L7/L12 of *Brucella* spp., have been shown to be immunogenic and to elicit a delayed-type hypersensitivity (DTH) response (Bachrach et al. 1994).

It is noteworthy that a recent study of Mizutani et al. (2000) suggested that a membrane fraction of *C. albicans* may act as an antigen which confers $CD4^+$ T-cell-mediated resistance to systemic candidiasis in mice. The 65 kDa mannoprotein described by La Valle et al. (2000) was also able to induce a cell-mediated immune (CMI) response (La Valle et al. 2000). A more recent study of Dromer et al. (2002) reported on the ability of synthetic analogs of β-1,2-oligomannosides of *C. albicans* to prevent intestinal colonization by the fungus.

Immune response

Exposure to *Candida* species stimulates both humoral and CMI responses. Anti-*Candida* antibodies can be detected in experimental animal infections, in humans with naturally acquired infections, as well as in healthy individuals harboring the fungus in a carrier state. The antibodies represent the different immunoglobulin types – IgG, IgM, IgA or IgE – albeit not all immunoglobulin types can be detected in all the clinical entities, under all conditions, and in different body fluids.

IgG and IgM are generally found in sera of patients with deep-seated forms of candidiasis, except if the patients are highly immunosuppressed and unable to mount an immune response. IgG and IgM antibodies can also be found in the mucocutaneous forms of candidiasis, as well as in asymptomatic carriers.

Anti-*Candida* IgE antibodies have been found in serum and in other body fluids in situations associated with allergy. In addition to measuring IgE antibodies in serum and other body fluids by serological tests, these antibodies can be revealed by skin testing with a *Candida* antigen. Skin inoculation with a *Candida* antigen may reveal an immediate type hypersensitivity (ITH) reaction resulting in the appearance of a flare-like erythema at the inoculation site 20–30 minutes after the test inoculation. The ITH response will be, generally, found in allergic states. An interesting observation was made by Witkin (Witkin et al. 1989) who noted the presence of IgE antibodies in women with vaginitis, indicating a possible role or association of ITH in the pathogenesis of vaginal infection.

IgA antibodies have been found in sera and vaginal secretions of patients with candidal vulvovaginitis (Schonheyder et al. 1983; Sobel 1985) and in vaginal fluids from experimentally infected rats (Polonelli et al. 1994; De Bernardis et al. 2002). However, the differences in the titers of IgA antibodies in patients in comparison to those of healthy individuals, or in other conditions with candidal colonization, are not discriminatory enough to permit the use of detection of this type of antibodies as a reliable diagnostic tool for candidal vaginitis.

As to CMI, a *Candida* infection or an asymptomatic colonization stimulates the response of the cellular immune system (Domer and Carrow 1989; Baum 1994). The CMI response can be detected by in vitro assays as well as by in vivo measurements. The current concept of the chain of events culminating in the expression of CMI postulates that PMNs produce IL-12, which stimulates Th1 cells to release interferon-gamma (IFN-γ) and IL-2, which activate phagocytes. In vivo measurements include skin testing with a candidal antigen (candidin). The CMI response thus measured will be expressed in a DTH reaction, revealing an indurated erythema at the site of the test-antigen inoculation, apparent about 48 hours postinoculation. As *Candida* do colonize healthy individuals, the skin test for detection of a DTH response will be positive in most of the tested individuals and cannot, therefore, serve as a tool for diagnosis of candidiasis. It can, however, indicate that the individual tested possesses an adequate cell-mediated immune system in order to mount the response to the antigen with which he/she was tested. Indeed, the *Candida* skin test is used to evaluate the CMI competence of patients. A negative candidin test will generally point to the inadequacy of the patient's immune system to mount a DTH response, and will suggest that the patient is immunodeficient or immunosuppressed. However, as there are different responses to different *Candida* antigens, this test must be interpreted with caution. CMI responses can be, as mentioned earlier, detected by several in vitro assays. The most commonly used assay is the lymphocyte transformation/proliferation test, which measures the in vitro stimulation of T lymphocytes with *Candida* antigens, indicating the sensitization of the CMI system by the fungus. This assay or other in vitro assays for detection of CMI response to *Candida*, similar to the skin test for in vivo evaluation of DTH, do not have marked value for diagnosis of candidiasis. However, as in the case of the skin test, the in vitro assays are useful for evaluation of the cell-mediated immune status of the individual. Moreover, the use of more than a single evaluation method, as for example a skin test and the in vitro lymphocyte transformation assay or the macrophage migration inhibition assay, may enable one to define more specifically the putative immune defect of the tested patient. This was demonstrated by Kirkpatrick (1989) in a series of studies of patients with chronic mucocutaneous candidiasis (CMC) in whom a differentiation of the individual immune defect(s) has been shown, revealing, for example, incompetence in antigen recognition versus inability to mount an immune response. The differentiation of different T-lymphocyte subsets (e.g. CD4, CD8) may also be of clinical relevance in evaluating the patients' immune status and possible susceptibility to *Candida* infection.

Immunity

Immunity to *Candida* infection, including the innate and adaptive defense system, is also a topic that has attracted considerable research interest. As can be judged by recent reviews (Romani 2002a, b) detailed, in-depth information on defense systems against candidiasis is emerging from studies undertaken during the last decade. Nevertheless, it is still difficult to draw clear and unequivocal conclusions. This might be due to the complexity of the topic and, partially, to the fact that most experimental evidence has been derived from animal models, among which divergences exist, and which do not necessarily correspond to human situations.

The contemporary view as to the innate versus adaptive immunity is that both should be looked upon as an integrated system. Immunity to *Candida* is currently believed to depend on various cells, including polymorphonuclear and mononuclear leukocytes, keratinocytes, and dendritic, epithelial, and endothelial cells. In addition, humoral elements, including antibodies, cytokines, and complement, are involved (Romani and Kaufmann 1998).

Among the T cells, the Th1 subset is the predominant cell population responsible for protection (Romani 1999). However, an important role in the immune response should be attributed to the Th2 subset as well.

It is believed that immunity is affected by the subtle interactions between the two subsets and their cytokines/chemokines. The current paradigm regarding events occurring following exposure to *C. albicans* yeasts includes the production, by PMNs, dendritic or other cells, of cytokines, which in turn induce Th1 cells to secrete cytokines activating effector cells. Among the cytokines, IL-2, IL-12, TNF-α, IFN-γ were reported to be of significance in protection against *Candida*. However, in superficial infections, local immunity at different anatomic sites apparently plays a significant role in immune response and defense to *Candida* (De Bernardis and Boccanera 2002).

MUCOSAL AND CUTANEOUS CANDIDIASIS

CMI plays a major role in the defense against mucosal and cutaneous *Candida* involvement. Indeed, CMI deficiencies as noted in AIDS or CMC patients result in increased susceptibility for development of cutaneous, nail, or mucosal candidiasis (Edwards 2000). As stated above, investigations of underlying mechanisms of CMI (Fukazawa et al. 1994) revealed the involvement of $CD4^+$ T lymphocytes, various cytokines, such as IFN-γ, IL-2 and 12, granulocyte-macrophage colony-stimulating factor (GM-CSF) (Smith et al. 1990; Watanabe et al. 1991; Romani and Kaufmann 1998; Romani 1999). Macrophages may act as effectors exerting their candidacidal effect following activation by IFN-γ produced by the Th1 CD4+ subset. It is also believed that oxygen radicals or cationic proteins or peptides released from the activated cells may be associated with the antifungal effect. In addition to CMI, antibodies have been shown to have a role in immunity as deduced from studies on experimental vaginitis in laboratory animals (De Bernardis and Boccanera 2002). A study by Fidel et al. (1995) pointed out, interestingly, that systemic CMI seems not to have a protective role in vaginitis (De Bernardis et al. 2002). Thus, apparently, defense against specific forms of superficial candidiasis may depend on different immune mechanisms, emphasizing the possibility of immunological compartmentalization.

DEEP-SEATED CANDIDIASIS

Immunity to deep-seated/systemic candidiasis does involve T-cell CMI as well; however, additional cellular and humoral elements seem to contribute significantly. This conclusion can be derived from the clinical–epidemiologic observations as to the individuals particularly susceptible to these forms of *Candida* infection. While, as indicated above, individuals with defects in the CMI system are especially prone to mucosal and cutaneous candidiasis, the other candidiasis forms are present mostly in neutropenic patients (Edwards 2000). It is, thus, evident that the PMNs are of importance in defense against these *Candida* infections. The role of granulocytopenia as a risk factor for systemic candidiasis was also demonstrated in experimental animal models, in which a neutropenic state was induced, revealing increased susceptibility to *Candida*. It is interesting that some studies (Fukazawa et al. 1994) have shown the involvement of both the Th1 and Th2 subsets of the CD4+ T cells in systemic *Candida* infection. A complex and not fully elucidated interaction between the two subsets takes place.

Extensive research has been devoted to the elucidation of the intricate role of cytokines in immunity to systemic *Candida* infections. The studies indicated that a major role might be attributed to IL-12, TNF-α (Mencacci et al. 1998), transforming growth factor beta (TGF-β) (Spaccapelo and Romani 1995) and IFN-γ (Cenci and Mencacci 1998) that are required for Th1 response induction (Mencacci et al. 1998). It should also be noted that different cytokines are induced by different *Candida* antigens (Cassone and De Bernardis 1998). Of interest are recent findings of Brieland et al. (2001). These researchers investigated the role of proinflammatory and anti-inflammatory cytokines in murine systemic candidiasis and showed that TNF-α played a significant role in protection against infection.

Phagocytosis and killing of *Candida* involve complement, antibodies, and various cytokines, such as IFN-γ or tumor necrosis factor (TNF) (Diamond et al. 1991) and granulocyte colony-stimulating factors (Kullberg and Anaissie 1998; Kullberg et al. 1998). Differences in the activity of phagocytes against the hyphal versus the yeast form have been described indicating increased efficacy of PMNs towards the blastospores (Romani and Bistoni 2002). It was also shown that phagocytosis of *C. albicans* yeasts by PMNs involve a mannose receptor. PMNs are known for their ability to kill *Candida* via oxidative burst, enzymatic activities such as myeloperoxidase, and defensins (Domer and Carrow 1989; Greenfield 1992). Intracellular killing of the phagocytized fungus seems to be more efficient in the presence of opsonins. Yeast cells surviving in murine macrophage may develop a germ tube, perforate the phagosome, and cause the cell's destruction (Kaposzta et al. 1999). Studies have shown the presence of specific receptor sites on *C. albicans* for CR2 and CR3 of the complement (Calderone et al. 1994; Hostetter 1994b), which could be involved in phagocytosis.

It has been postulated by Matthews (Matthews et al. 1988) that anti-*Candida* antibodies found in sera of AIDS patients directed against a 47 kDa candidal antigen might have a protective role (see the following section on Immunization below).

Immunization

Experimental animal models have indicated that sublethal *Candida* infections may induce partial immunity to reinfection (Giger et al. 1978; Oblack and Holder 1979), an observation that indicated that obtainment of

adaptive immunity could be feasible. This was the rationale for various attempts to induce protection against *Candida* infections by immunization with a fungal antigen. Various fungal preparations, including live, attenuated or killed organisms, subcellular components, and defined antigens have been explored as possible immunogens (Segal 1994a). Various routes and procedures of immunization have been investigated as well. It is not practical, nor is it purposeful, within the scope of this chapter to detail all these studies, and the specifically interested reader should refer to relevant bibliography.

It should be noted that although, despite the efforts, no clinically available anti-*Candida* vaccine of proven efficacy has yet been obtained, some recent developments seem promising. These are related, particularly, to the possibility of using anti-*Candida* antibodies in immunotherapy and/or immunoprophylaxis of systemic candidiasis, based on the observations of Matthews and colleagues (Matthews et al. 1988) indicating a possible role for anti-*Candida* antibodies in resistance to systemic candidiasis. A specific *Candida* antigen, the heat shock protein 90 (HSP90), was identified as an immunodominant antigen that elicits protective antibodies (Matthews et al. 1991, 1995). Use of molecular engineering technology enabled production of a human antibody, which is being evaluated in human clinical trials (Matthews et al. 2000; Matthews and Burnie 2001; Rigg et al. 2001) (under the designation 'Mycograb') as an adjunct to antifungal therapy and possible immunoprophylaxis in compromised patients (Matthews and Burnie 2001). Other investigators have also suggested the usefulness of anti-*Candida* antibodies (Cutler et al. 2002). Cutler and colleagues demonstrated that antibodies to a mannan–protein complex, encapsulated in liposomes, protected mice against challenge with the fungus.

Various attempts to immunize against candidiasis have been undertaken for several decades and have been summarized previously (Segal 1987b, 1991). Among these were studies on the ribosomal fraction of *C. albicans* as immunogen (Segal 1987b, 1991), revealing their protectivity. Based on this background, Levy et al. (1989) found that supplementing *C. albicans* ribosomes with a cell wall fraction from *Klebsiella pneumoniae*, an adjuvant permissible for human use, augmented the efficacy of the vaccine.

The group of Segal (Eckstein et al. 1997) investigated the use of liposomal particles as carriers of the *C. albicans* ribosomes. The efficacy of ribosomes incorporated into liposomes, with and without addition of lipid A, was compared to that of ribosomes, and incomplete Freund's adjuvant (IFA), revealing that the liposomal preparations were as effective as ribosomes and IFA. Thus, *C. albicans* ribosomal particles have the potential for human use.

Glyceraldehyde-3-phosphate-dehydrogenase (GAPDH) was found to be a surface antigen (Gil-Navarro et al. 1997) that binds to fibronectin and laminin (Gozalbo et al. 1998) and is expressed in vitro and in infected tissues (Gil et al. 1999). The possibility to generate 'humanized' antibodies, using *Candida* GAPDH as an immunogen, has been recently suggested (Priel et al. 2002).

PATHOLOGY AND HISTOPATHOLOGY

Many *Candida* spp., notably *C. albicans*, are part of the normal microflora of various mucosal surfaces. Consequently, pathology caused by these yeasts is a result of one or more underlying predisposing factors which:

- impair, to various degrees, the immune response to these microorganisms (metabolic diseases, AIDS, immunosuppressive chemotherapy)
- produce an imbalance, in favor of the fungal microflora (antibacterial drugs), or
- damage the integrity of the integument (surgery, intravenous catheters).

The macroscopic and microscopic appearance of lesions caused by *Candida* spp. is primarily influenced by the interaction of three factors:

1. the site of infection
2. the pathogenicity of the infecting microorganism and to a lesser extent its species
3. the competence of the host's immune system.

Consequently, pathological and histopathological features of *Candida* infections are highly variable: the same microorganism may cause dissimilar pathological lesions in patients whose immune system is intact and in those who are in a state of immunosuppression. Nevertheless, certain common pathological characteristics of *Candida* infection may be described (Salfelder 1990; Luna and Tortoledo 1993)

Superficial infections

Superficial infections result from invasion of the superficial layers of skin and/or mucosae by the microorganism. Macroscopically these infections are characterized by the formation of a grayish plaque, surrounded by edema, which, at histopathological examination, consists of the infecting microorganism, neutrophils, and cell debris.

In deeper ulcerative lesions of the mucosae, such as those of the digestive system (especially the esophagus) often observed in immunosuppressed patients, the infecting microorganism may be present in the submucosa and may reach blood vessels and be disseminated hematogenously. The cellular reaction to the infection is limited or absent, and necrosis, typically accompanied by hemorrhage, are the salient microscopic features of *Candida* infection in these patients.

A special form of superficial infection, chronic mucocutaneous candidiasis, is characterized by the formation of warty proliferation of the skin, which results from hyperkeratosis and epithelial hyperplasia. Granulomatous tissue may be formed in the subcutis.

Deep infections

Several parenchymatous organs may be involved. These infections are characterized by microabscesses, macroscopically similar to miliary tuberculosis in which the microorganism may be individuated as blastospores and/or pseudohyphae (the latter absent in *C. glabrata* infections), neutrophils, and mononuclear cells, and a necrotic center. Granulomata with giant cells and lymphocytes may be formed in chronic infections.

Although various organs (such as liver, spleen, and brain) (Figure 3) may be affected in disseminated *Candida* infections, kidneys seem to be target organs of *C. albicans*, presenting nephritis, pyelonephritis, and, more rarely, papillary necrosis. Infection may be ascending or hematogenous. The former is a frequent sequel to prolonged catheterization and antibacterial therapy. It is characterized by small white lesions, especially in the medullar part of the kidney. Histopathological examination of these lesions reveals the presence of the infecting agent in the tubules, invading the surrounding parenchyma through the tubule's wall. When the spread of the infecting agent is hematogenous, the lesions are evenly distributed between cortex and medulla, lesions in the lower urinary tract are typically absent, and, microscopically, fungal elements may be noticed in the glomeruli.

Candida endocarditis, often a sequel to intravascular catheterization or prosthetic valve implantation, is characterized by vegetations on the surface of the endocardium, especially the mitral valves. The composition of these vegetations may vary and they consist of blood clots, cell debris, and fungal elements. Microabscesses may develop in the myocardium and evolve, in chronic cases, to granulomata.

Liver and spleen lesions are typically larger than those observed in other organs and may be detected by computerized tomography or other related techniques. Microbscesses characterize the acute stage of the infection, whereas granulomatous lesions without many organisms may develop in the chronic forms.

CLINICAL ENTITIES

Candida species can cause a range of clinical forms, from superficial manifestations involving skin, nails, and mucosal surfaces to deep-seated infections involving various internal organs and to disseminated disease (Odds 1988; Rippon 1988; Kwon-Chung and Bennett 1992; Bodey 1993; Edwards 2000). For the sake of simplicity, clinical entities can be subdivided into two large groups:

1. mucocutaneous candidiasis
2. deep-seated candidiasis.

Mucocutaneous candidiasis

Mucocutaneous candidiasis can be further subdivided into:

- cutaneous infections
- nail infections
- mucosal infections,

each group including a number of specific clinical forms.

It is evident that such a division is, to a certain degree, artificial, since in certain clinical forms, more than a single system can be involved. For example, patients suffering from CMC can present clinical manifestations on the glabrous skin, on mucosal surfaces, and in the nails. This may also apply, to some degree, to nail infection, which can include also the surrounding skin area (paronychia).

CUTANEOUS INFECTIONS

Based on the dermatological classifications (Goslen and Kobayashi 1993), the major syndromes considered here are:

- candidal intertrigo
- interdigital candidiasis
- perianal (diaper) rash
- candidids
- CMC.

As tabulated by Odds (1988), *C. albicans* is the most commonly isolated species from most forms of cutaneous involvement. However, other pathogenic *Candida* spp., such as *C. tropicalis*, *C. guilliermondii*, *C. kefyr*, *C. krusei* and *C. parapsilosis* are also known to be involved. If not otherwise specifically stated, the descriptions given below apply to *C. albicans*, as well as to other *Candida* spp.

Candidal intertrigo

Candida intertrigo is believed to be the most common clinical form of the cutaneous infection, as *Candida* spp. readily colonize skin folds, particularly in moist and macerated sites (Hymes and Duvic 1993; Edwards 2000). These may include ear folds or the submammary, crural, and axillary areas. The lesions are erythematous, with vesicles and pustules, in combination with pruritus.

These infections are frequently associated with specific predisposing conditions (Odds 1988; Wagner and Sohnle 1995), such as obesity, diabetes mellitus (Montes 1992), various endocrine disturbances, HIV infection

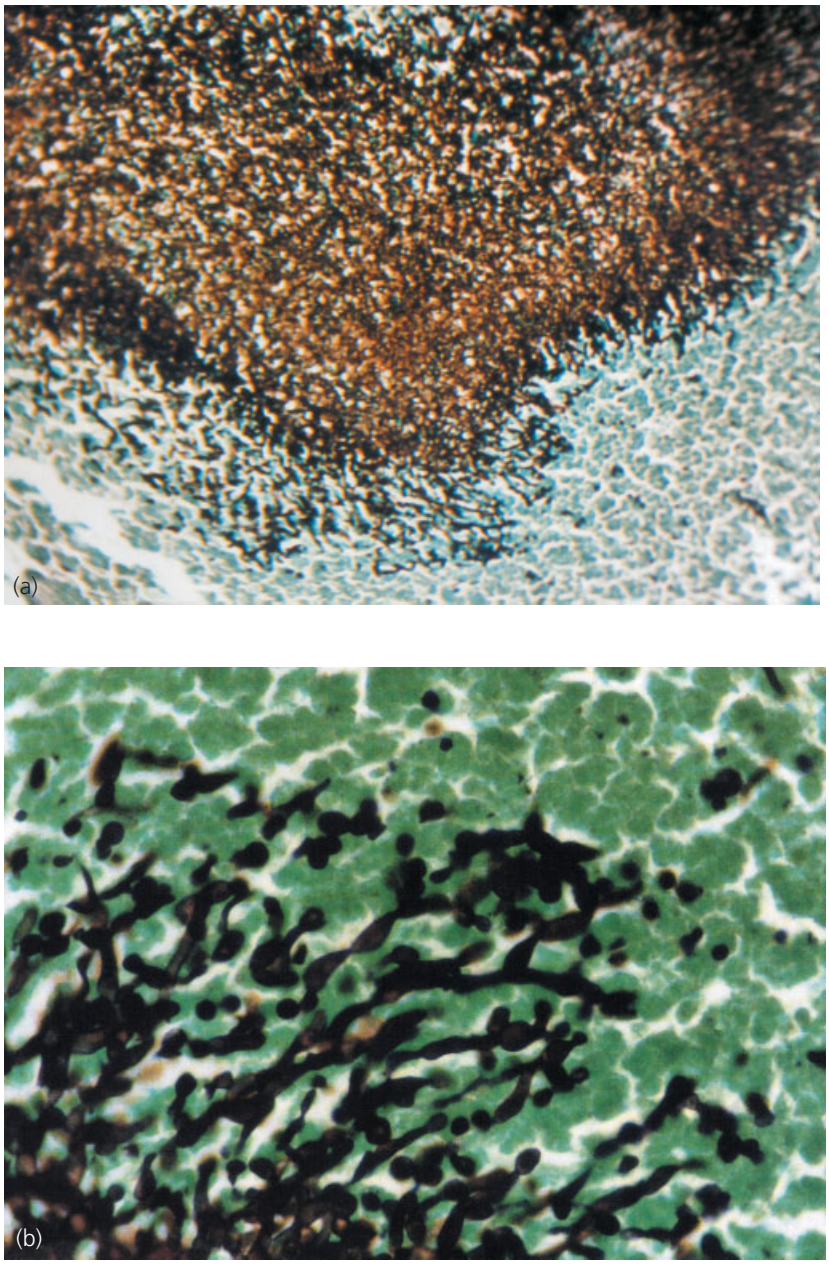

Figure 3 *Hepatic candidiasis:* **(a)** *candidal lesion;* **(b)** *candida mycelial and yeast elements. GMS. (Courtesy Professor Salfelder, Venuzuela)*

(Odds et al. 1990) or various iatrogenic factors including antibacterial and steroid therapy.

Interdigital candidasis

Among the intertriginous areas affected by *Candida*, the skin folds between the fingers of the hands should be particularly mentioned. In this form the skin folds between the fingers are macerated and itching. This condition is associated with excessive exposure to moisture, and thus seen particularly among dishwashers, bartenders, and fruit cannery workers. A similar erosive rash may occur between the toes in hot climates.

Perianal (diaper) rash

Another clinical form associated with *Candida* is that involving infants wearing diapers, in whom rashes are seen in the perianal area and on the buttocks. It should, however, be pointed out that diaper rash is not associated exclusively with *Candida*, and it is possible that the organisms are secondary to a preexisting inflammatory condition.

Candidids

A less commonly seen clinical form involves lesions mediated by the host's immune response to the infection – the candidids (Rippon 1988). These may be considered allergic responses, similar, albeit less frequent, to that noted in dermatophyte infections (the dermatophytids). Generally, with the treatment of the *Candida* infection, the candidid reaction clears.

Chronic mucocutaneous candidiasis

This paragraph will refer only to the cutaneous manifestations of chronic mucocutaneous candidiasis (CMC), while the other manifestations (mucosal and nail), which can also be associated with this form, as stated above, are covered later under the appropriate sections.

CMC is a relatively rare condition, however extensively studied, particularly by Kirkpatrick (1989, 1993), since it is considered the most severe clinical entity of the superficial candidiasis forms, and associated with a set of specific predisposing factors. Most of the cases are known to be caused by *C. albicans*.

The predisposing factors include, generally, congenital immunological or endocrinological defects. The immunological defects are mostly in CMI, which can be either at the stage of general or specific antigen recognition, and/or response to the antigen. This can be expressed in defects of T-lymphocyte activation and/or cytokine production leading to impairment of macrophage activation.

Clinically, the entity is characterized by the presence of persistent lesions, with high rate of recurrence, starting in early childhood and possibly persisting throughout the individual's lifetime. Lesions can be seen on various skin sites, and are not limited particularly to skin folds as in the other cutaneous forms of candidiasis. CMC can appear in a generalized form or can be localized and assume a form of hyperkeratotic lesions – '*Candida* granuloma.'

An interesting feature of CMC, from which conclusions as to the immune-defense mechanisms in candidiasis have been drawn, relates to the phenomenon that CMC patients, who may suffer from extensive cutaneous, nail, and/or mucosal infections, do not develop deep-seated or systemic candidiasis. It should be added in this context that AIDS patients, who frequently also suffer from severe and repeated mucocutaneous candidiasis, and may thus be considered in a similar category as CMC patients (Filler and Edwards 1993), do not generally develop systemic candidiasis.

This observation led to the hypothesis that, apparently, the immune-defense mechanism in candidiasis differs for the mucocutaneous versus the deep-seated forms (Domer and Lehrer 1993). It is thus believed that, while the resistance to the mucocutaneous forms is based, primarily, on intact and adequately functioning CMI, particularly, that associated with T-cell activity, resistance to deep-seated and systemic candidiasis involves additional factors. The CMC condition, in addition to serving as a relevant 'in vivo model' for providing valuable insights on the immune-defense mechanisms in candidiasis, was also one of the few entities in which various immunomodulating substances, such as transfer factor (Kirkpatrick et al. 1976; Mackie 1979) or thymosin (Wara and Amman 1978), have been evaluated as possible therapeutic approaches.

NAIL INFECTIONS

Under this section two syndromes are discussed: *Candida* onychomycosis and paronychia (Haneke 1986; Hymes and Duvic 1993).

Paronychia

Paronychia is an infection of the nail folds. It is a condition characterized by an inflammation with painful, erythematous, and swollen nail folds. It generally appears around the nails of the hands and less frequently on those of the feet. Nail plate involvement can follow, but not necessarily. *C. albicans* is the major etiologic agent; however, *C. parapsilosis* and *C. guilliermondii* are also recognized agents of this syndrome. Secondary bacterial infections are a known complication.

Paronychia is often seen in patients who also suffer from erosio interdigitalis. Similar to erosio interdigitalis, it is associated with excessive water immersion and is therefore seen in a similar population segment: dishwashers, bartenders, and fruit cannery workers. It can thus be considered, to some degree, an occupational disease. CMC patients often suffer from paronychia. Paronychia is more frequent among women than among men.

Onychomycosis

As in paronychia, involvement of the nail itself by *Candida* is more often seen in nails of the hands. The affected nails may become discolored, eroded, brittle, detached from the nail bed, and painful. Generally there is less accumulation of debris under the nail plate than in dermatophyte onychomycosis; however, the condition is more painful. In most instances the infection begins with the nail fold involvement, although as indicated above, not all the paronychia cases do lead to onychia. Candida onychomycosis is caused by the same *Candida* species as paronychia, and is more frequent among women. It is seen in CMC patients and in immunosuppressed patients or those with symptomatic peripheral vascular disease.

MUCOSAL INFECTIONS

Involvement of mucosal surfaces by *Candida* is considered the most frequent clinical manifestation of

candidiasis. Although the term mucosal surfaces encompasses in the strict sense of the word mucosal membranes of various organs, what is generally understood by the term mucosal candidiasis is involvement, primarily, of the oral and vaginal mucosa. Thus, the following section covers *Candida* infections of these two mucosal sites, while additional mucosal manifestations will be dealt elsewhere, under the appropriate sections.

Oral candidiasis

Candidiasis of the oral mucosa (Samaranayake and MacFarlane 1990; Lynch 1994; Cannon et al. 1995) is a disease recognized since antiquity, which has gained renewed significance more recently as an infection frequently seen in AIDS patients and in other conditions. As cited by Samaranayake and Macfarlane (1990) in their monograph on oral candidiasis, the renewed interest in this infection is expressed in the large number of scientific papers published in the last two decades.

Although *C. albicans* is, as in other types of *Candida* infection, the most frequently isolated etiological agent, additional *Candida* spp., such as *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. guilliermondii*, are also implicated in oral candidiasis (Bodey 1993). It should be emphasized, however, that these species can also be isolated from the oral cavity of normal individuals without obvious pathology. This observation, which demonstrates the complexity of the diagnosis, is relevant also to other anatomic sites, such as the vagina.

Oral candidiasis can be clinically classified into several different forms:

- acute pseudomembranous candidiasis
- acute atrophic candidiasis
- chronic atrophic candidiasis
- chronic hyperplastic candidiasis
- angular cheilitis.

Oral candidiasis of several clinical forms, mostly of chronic nature, is seen in patients with CMC. It can assume the pseudomembranous or hyperplastic form, with or without angular cheilitis. It can also, similar to the situation in AIDS patients, spread to the esophageal mucosa.

Acute pseudomembranous and acute atrophic candidiasis

Acute pseudomembranous candidiasis, known also under the term oral thrush, is manifested by white-gray lesions on the gums, tongue, or oral mucosa, which can appear as single lesions or as confluent large plaques. The lesions, particularly when covering larger areas, may be painful, and disturb intake of food. They may spread to the mucosa of the esophagus, as seen in a significant number of AIDS patients, and cause dysphagia. In addition to AIDS or cancer patients and otherwise debilitated individuals, the infection is generally present in infants, particularly those born to mothers suffering from vaginal candidiasis, and in the elderly.

Acute atrophic candidiasis is characterized by painful, erythematous mucosa, particularly on the tongue, which can be associated with loss of the tongue papillae, affecting food intake. Acute atrophic candidiasis may follow the acute pseudomembranous form with the disappearance of the pseudomembranous lesions. It can appear as a sequelae of antibiotic treatment.

Chronic atrophic and hyperplastic candidiasis

Chronic atrophic oral candidiasis, known also as denture stomatitis, is frequently seen in elderly individuals (Cumming et al. 1990), particularly those wearing dentures, and is reported in a very high proportion of this group. It is believed to be the most common clinical form of oral mucosa involvement. Clinically it is characterized by erythema and/or edema of the mucosa under the dentures, and generally, contrary to acute atrophic candidiasis, is not painful.

The chronic hyperplastic form, termed also *Candida* leukoplakia, is a much rarer condition. It presents with white plaques, which can appear on various sites of the buccal mucosa, and contrary to the acute pseudomembranous form, can not be removed. The importance of this clinical entity lies in the association with possible transformation into a malignant state.

Angular cheilitis

Clinically this form is characterized by erythema and fissures at the folds of the corners of the mouth. It may accompany other clinical forms of oral candidiasis, such as denture stomatitis or oral thrush. When accompanying denture stomatitis its appearance is attributed to unfitting dentures, which create the appropriate physical conditions for development of this type of infection. It is also believed that angular cheilitis may be associated with avitaminosis.

VAGINAL CANDIDIASIS

Candidal vulvovaginitis (Odds 1988; Sobel 1992a, b, 1993; Edwards 2000) is a common female infection, primarily during the fecund period. It is believed to be the most frequent or second most frequent vaginal infection, depending on geographical area, and its incidence is estimated in the range of 5–20 percent. The incidence increases in particular groups, such as pregnant or diabetic women, those using oral contraceptives or who are post antibiotic treatment. The predisposing factors believed to be associated with this specific condition can be associated primarily with the host and also with some virulence attributes of the pathogen. The former may include hormonal effects as seen in pregnancy, immunological or nutritional factors (Witkin et al. 1983, 1986, 1989). The latter may be correlated with certain fungal

factors, such as increased adherence ability (Segal et al. 1984).

Besides *C. albicans*, *C. glabrata* and *C. tropicalis* are the most frequently isolated *Candida* spp. (Horowitz et al. 1992) both from vulvovaginitis patients and from healthy carriers. Again, as already stated, here too the problem of microbiological diagnosis is demonstrated.

Clinically the syndrome includes complaints of vulvovaginal pruritus and discharge, which can be thick and 'curd-like' or thin. The infection may be associated with erythema of the vulvovaginal mucosa and possibly also of the perianal area. The lesions on the mucosal surface are basically adherent plaques. The condition may cause discomfort and pain during intercourse.

An important feature of candidal vulvovaginitis is the recurrence of the infection, although the majority of vulvovaginitis cases will respond to treatment. Chronic, recurrent vaginal candidiasis poses a medical problem and was quite extensively studied, as to possible risk or predisposing factors, and fungal reservoir (Sobel 1992b).

Sexual transmission to a male partner is known (Sobel 1993). In the male the infection presents, generally, as a balanitis with lesions and erythema on the penis.

Deep-seated candidiasis

The term deep-seated candidiasis (Odds 1988; Bodey 1993; Edwards 2000) refers to infection of visceral organs and possibly to multiple-organ or disseminated disease. Basically, any organ or system can be affected, thus the clinical entities may include: candidiasis of the gastrointestinal tract, respiratory system, central nervous system, renal and urinary tract, cardiovascular system; hepatosplenic candidiasis; hematogenous disseminated disease; ocular infections; and a variety of other specific manifestations. As it is impossible to cover all the clinical manifestations, the description here is limited to the major clinical entities.

CANDIDIASIS OF THE GASTROINTESTINAL TRACT

Esophagitis

This syndrome (Musial et al. 1988) includes painful dysphagia and possibly chest pain. Additional symptoms may include nausea and/or vomiting. White patches, which resemble those of oral candidiasis, can be noted by endoscopy on the esophageal mucosa. Esophagitis may be associated with presence of oral candidiasis, but may also present as a separate clinical entity without oral involvement.

The frequency of this syndrome increased since the appearance of AIDS. It is estimated that 10–30 percent of AIDS patients with oral candidiasis may suffer also from candidal esophagitis. The infection is also seen in cancer patients following anticancer therapy.

Gastrointestinal candidiasis

As stated earlier, *Candida* spp., primarily *C. albicans*, *C. glabrata*, or *C. tropicalis*, colonize the gastrointestinal (GI) tract in a significant proportion of normal individuals (Stone et al. 1973; Bolivar and Bodey 1985; Odds 1988) as judged by fungal isolation from feces. An increase in the percentage of colonized individuals is noted among hospitalized patients (Kusne et al. 1994).

Clinical involvement of mucosal surfaces of the stomach and/or small and large intestine, with mucosal white plaques and ulcerations are found primarily in cancer patients. A large survey conducted by Eras et al. (1972) on cancer patients, including postmortem studies, revealed involvement of stomach and intestines.

As already mentioned, *Candida* GI colonization and infection are believed to play a role in the pathogenesis of development of disseminated candidiasis. The GI tract can serve as a reservoir for the fungus, from where it can spread, particularly if there is a breach in the intactness of the mucosal lining. In patients with malignancies, there are several factors contributing to an increased risk of dissemination. These include increased *Candida* GI colonization, as these patients are generally treated with antibiotics, which change the GI flora in favor of *Candida*, and impairment of the GI mucosa, mostly due to anticancer therapy. Furthermore, such individuals may also have deficiencies in the activity of the immune system, both due to the neoplastic process itself and as possible sequelae of the anticancer treatment, therefore being unable to overcome the infectious agent once it was introduced. Thus, GI colonization and infection in cancer patients or in other categories of debilitated individuals, such as organ transplant patients (Kusne et al. 1994), is of particular significance and should be monitored and, if possible, controlled.

The possibility that *Candida* colonization may cause diarrhea is speculative, although reports in this regard are found in the literature (Talwar et al. 1990; Enweani et al. 1994; Levine et al. 1995).

Candidiasis of the liver, spleen, and other organs

Hepatosplenic candidiasis, which can be considered also as part of a disseminated infection, became a recognized clinical entity recently (Haron et al. 1987; Thaler et al. 1988; Edwards 2000). It is seen primarily in leukemics, with the hepatosplenic involvement becoming apparent generally during recovery from the neutropenic state, while the infection started during the patient's neutropenic period. This clinical entity is difficult to diagnose and manage. Diagnosis can be assisted by computed tomography (CT) scans demonstrating lesions in the liver and the spleen, and by biopsied tissues revealing the presence of fungal elements. Most cases are caused

by *C. albicans*; however, infections by other species have also been described (Pines et al. 1994).

Other organs of the GI system affected by *Candida* include the gallbladder and pancreas. In this connection peritonitis due to *Candida* should also be mentioned, which occurs particularly in patients on peritoneal dialysis (Yuen et al. 1992; Amici et al. 1994).

CANDIDIASIS OF THE RESPIRATORY SYSTEM

Respiratory *Candida* infections involving the lungs or bronchial system appear predominantly in patients with underlying primary diseases (Masur et al. 1977; Gueteau et al. 1991). Bronchopneumonia can originate from hematogenous spread of the fungus as part of a disseminated infection or from introduction of the pathogen into the lung. Diagnosis is difficult as *Candida* can be found in the sputum of individuals without candidiasis, so that it is pertinent to demonstrate the presence of the fungus in bronchopulmonary tissues.

CANDIDIASIS OF THE CARDIOVASCULAR SYSTEM

Candida spp. can cause clinical manifestations in various organs of the cardiovascular system (Musial et al. 1988; Kwon-Chung and Bennett 1992; Edwards 2000): the pericardium, myocardium or endocardium, with endocarditis being the best-known clinical entity.

Endocarditis (Hallum and Williams 1993; Wilson H.A. et al. 1993) is seen primarily in intravenous drug addicts and in individuals with impaired or prosthetic heart valves. It was also described in patients following various cardiac surgery procedures or as sequelae of anti-cancer therapy. Due to the increase in drug addiction and frequency of cardial surgery, an increase in the incidence of *Candida* endocarditis was noted.

Endocarditis can be caused by *C. albicans* and other species, such as *C. parapsilosis* (Cancelas et al. 1994) and *C. tropicalis*. Interestingly, non-*albicans Candida* infection is seen mostly in heroin addicts. It is possible that the infection originates from contaminated heroin. In the other susceptible groups, such as those with impaired or prosthetic valve patients, the infection may originate from introduction of the fungus during the surgical procedure, with the prosthetic or impaired valve serving as a suitable substrate to which *Candida* can readily adhere and form the typical vegetations.

Clinically, candidal endocarditis is difficult to differentiate from that caused by bacteria. It may, however, have a more prolonged onset; e.g. in post-surgery patients it may become apparent months later. The patients present with fever, heart murmurs, possible blood vessel obstruction, splenomegaly, and typical endophthalmitis. Pathologically, *Candida* endocarditis is characterized by large vegetations, from which emboli may be released.

RENAL AND URINARY TRACT CANDIDIASIS

Lower urinary tract infection

Candida lower urinary tract infection (UTI) (Musial et al. 1988; Gentry and Price 1993) is quite frequently seen in association with indwelling catheters, and may originate from the GI tract or genital flora. It is, thus, more frequently seen in females. The infection is also found in diabetics.

The symptoms are not unique and the course of the infection can be mild or more severe. An interesting clinical feature is the possible formation of fungal masses, 'fungus balls' (Scerpella and Alhalel 1994), which may cause obstruction and impair normal urine flow.

A basic problem associated with the diagnosis of this entity is the significance of candiduria in respect of discriminating infection from colonization due to contamination with flora of adjacent anatomic sites. Quantitative assessment of *Candida* colony-forming units (CFU.) in urine may be helpful, but does not always provide a definitive unequivocal answer.

Renal infection

Renal candidiasis (Edwards 2000), can, theoretically, originate from hematogenous *Candida* dissemination or as an ascending UTI. In reality, however, the latter is quite a rare event, and most of the cases of renal involvement come from hematogenous spread.

Pathologically, as mentioned in the relevant section, renal candidiasis is characterized by microabscess formation, mostly evident in the cortex of the kidneys. Similar pathology is noted in experimental *Candida* infections in animal models. The kidneys are a target organ for the fungus in infections induced by different ways of inoculation (intraperitoneal or intravenous).

CENTRAL NERVOUS SYSTEM CANDIDIASIS

Central nervous system (CNS) involvement by *Candida* (Walsh et al. 1985) is uncommon and is limited predominantly to *C. albicans*. The most susceptible individuals are AIDS patients and premature infants (Fakes 1984; Baley et al. 1986; Hughes et al. 1993; Edwards 2000). The CNS is generally seen as part of disseminated candidiasis involving in most cases primarily the meninges, although abscess formation in brain tissue was also reported.

Candida meningitis patients may present with symptoms similar to those seen in meningitis of other etiology, including various neurological abnormalities. *Candida* organisms may be detected microscopically in direct smears from the cerebrospinal fluid (CSF). In addition, abnormal protein and/or sugar values may be found in the CSF.

DISSEMINATED CANDIDIASIS AND CANDIDEMIA

Disseminated candidiasis can be defined as a multiorgan infection including possible candidemia, although blood cultures do not always yield the fungus. As already stated in the previous sections, disseminated candidiasis may include involvement of the CNS, kidneys, heart, eyes, or other organs and systems. As previously indicated, hepatosplenic candidiasis, although dealt with in an other section, is a specific clinical manifestation of disseminated infection.

Disseminated candidiasis caused by *C. albicans* and other species is associated with debilitation. It is seen in cancer patients (Musial et al. 1988), particularly those with acute leukemia (D'Antonio et al. 1992), in patients post-surgery, particularly GI and cardiac surgery, in transplant patients, particularly bone marrow transplants, in premature infants (Walter et al. 1990), burn patients (Green et al. 1994), and drug addicts.

Candidemia may present with the unspecific symptoms of a septic state, including fever. Presence of cutaneous and ocular involvement may be helpful diagnostic criteria. Candidemia patients may present (Edwards 2000) with nodular lesions on the skin and typical white lesions in the retina. These criteria are of particular importance, as cultural evidence of fungal etiology may be lacking.

Ocular *Candida* infections

Candida species can affect both the outer and inner eye (Langenhaeck and Zeyen 1993; Romano and Madjarov 1994). Infection may originate from hematogenous dissemination or from direct fungal introduction, the first, generally resulting in inner-eye infection, and the latter in clinical manifestations of the outer parts of the eye. Both categories of eye involvement are caused by *C. albicans* and some other *Candida* species, such as *C. parapsilosis*, *C. krusei*, and *C. glabrata*.

Outer-eye infections could also be considered in the section on superficial mucocutaneous candidiasis. These include infections of the conjunctiva (conjunctivitis), cornea (keratititis), eyelids (blepharitis), or lacrimal duct (lacrimal canaliculitis). Such infections may be associated with some ocular trauma, such as surgery, injury, or even the use of contact lenses. *Candida* infections may also follow other ocular infections, such as herpes simplex, or appear as sequelae of corticosteroid or antibacterial treatment.

Endophthalmitis, as indicated above, is generally a result of hematogenous fungal spread (McQuillen et al. 1992; Cohen and Montgomerie 1993), although it may also result from an exogenous source. The infection can cause loss of vision and is characterized by presence of typical white cotton-like lesions, which, as indicated, are an important diagnostic criterion for disseminated candidiasis.

ANIMAL DISEASE

Candida spp. may constitute part of the normal microflora in various anatomic sites, such as the digestive and genital tracts, skin, and ears (Yeruham et al. 1999; Duarte et al. 2001), of animals. Consequently, their involvement in pathological processes is secondary, often as a sequel to prolonged antibacterial chemotherapy, stress, and substandard management practices such as overcrowding and bad nutrition. Immune insufficiencies, of primary importance as predisposing factors to human mycotic infections, seem to have a more limited significance in animals. Nevertheless, the possibility of correlation between hereditary immunodeficiency in foals (McClure et al. 1985) and *Parvovirus*-induced immunosuppression in dogs (Anderson and Pidgeon 1987) has been suggested.

Most *Candida* infections, which have been described in animals, can be grouped into three principal categories as follows.

Candidiasis of the digestive tract

Esophagogastric candidiasis has been reported in various animal species. *C. albicans* and other non-specified *Candida* spp. have been isolated from pigs suffering from ulcers related to altered keratinization of the esophagogastric tract more frequently than from healthy animals (Kadel et al. 1969). The ability of *C. albicans* to utilize keratin as sole nitrogen source has been suggested as an explanation for this observation (Kapica and Blank 1957). Other possible predisposing factors to esophagogastric candidiasis in swine may be bad management, overcrowding, and antibacterial chemotherapy.

Other animals from which *Candida* spp. were isolated from esophagogastric lesions are foals (Gross and Mayhew 1983) and calves (Cross et al. 1970; Elad 1993). *C. glabrata* was found to colonize the abomasums of preweaned calves, possibly being involved in neonatal calf diarrhea (Elad et al. 1998). Colonization was more frequent and shedding more intensive in calves fed with milk replacers than in those fed dam's milk (Elad et al. 2002).

Candida spp., especially *C. albicans*, may be part of the normal flora of the avian digestive tract. However, they may be also involved as primary pathogens or as secondary invaders of damaged mucosa (such as is often the case in force-fed geese), in infections of various parts of this system, especially the crop. These infections may unsettle the function of the digestive tract and cause vomiting, increase in crop emptying time, and impaction. Antibacterial chemotherapy is assumed to play an important role as a prediposing factor to avian candidiasis by changing the microbial balance. The outcome depends primarily on the immune competence of the

host (Ritchie et al. 1994), influenced by environmental factors such as stress and captivity. *Candida* infections of birds, in sites other than the digestive tract, have been reported sporadically (Ritchie et al. 1994). In addition to *C. albicans*, other *Candida* spp. have been reported to be involved in avian candidiasis (Moretti et al. 2000), albeit more rarely.

Candidiasis of the urogenital tract

Candida spp. have been reported to be part of the normal flora of the genital tract of various animals (Chengappa et al. 1984), but have been associated with cases of bovine abortion (Foley and Schlafer 1987) and reduced fertility in cattle (Panangala et al. 1978; Sinha et al. 1980; Sutka 1983; Foley and Schlafer 1987; Tainturier et al. 1993) and horses (Abou-Gabal et al. 1977). The isolation of *Candida* spp. from aborted bovine fetuses is rare relative to other pathogens, including hyphomycetes, but has a worldwide distribution (Foley and Schlafer 1987). *C. tropicalis*, *C. albicans*, *C. krusei*, and *C. parapsilosis* are among the species isolated from such cases.

C. albicans as the causetive agent of cloaca and vent infections of geese and turkeys has been reported (Beemer et al. 1973; Marius-Gestin et al. 1987).

Candida mastitis

Candidal mastitis is usually self-limiting with spontaneous recovery and the infection has usually no systemic consequences. *Candida* spp. have been isolated from milk sampled from cattle with and without signs of mastitis. Most cases are sporadic but outbreaks have been reported (Elad et al. 1995). These were usually associated with intramammary instillation of contaminated antibacterial preparations, usually home made under nonhygienic conditions (Kirk et al. 1986). However, heavy environmental contamination with the yeast, in conjunction with insufficient milking hygiene, have been suspected of precipitating such outbreaks (Elad et al. 1995). All the yeast species dealt with in this chapter (and many others) have been isolated from cases of mycotic mastitis. *C. krusei* seems, however, to be more prevalent than other species in many reports. This might be the consequence of this species' relatively high environmental prevalence, especially in silage, where it may thrive during certain stages of anaerobiosis development, by using lactic acid as carbon source (Burmeister and Hartman 1966).

In addition, unique yeast infections, such as pyothorax (Fales et al. 1984) and urocystitis (Fulton and Walker 1992) in two cats, enteritis in a dog (Anderson and Pidgeon 1987), and keratitis in a horse (Desbrosse 1994), all caused by *C. albicans*, have been reported. In wild animals, *C. albicans* has been isolated from marine mammals (Sweeney et al. 1976), wild birds, marsupials, and reptiles.

LABORATORY DIAGNOSIS

Laboratory diagnosis of candidiasis depends upon the nature of the different clinical entities, specifically, whether they are mucocutaneous or deep-seated forms. Thus, the discussion of laboratory diagnosis will be in reference to the two groups of clinical manifestations.

Mucocutaneous candidiasis

Laboratory diagnosis of the different clinical forms of mucocutaneous candidiasis, which follows the clinician's diagnosis of suspected *Candida* involvement of the skin, nails, or mucosal surfaces, includes, generally, two steps:

1. direct examination of pathological specimen to demonstrate fungal presence
2. isolation of the fungus in culture and its identification.

DIRECT EXAMINATION

Skin and nail infections

Clinical specimens from diseased skin or nails can be collected by scraping the affected area, or, in some instances, by the use of swabs; material from nails can also be obtained by cutting the infected nail (Merz and Roberts 2003).

The preferred method for direct examination of clinical specimens from cutaneous and nail candidiasis is the wet mount technique. Specimens have, in most cases, to be treated with a keratinolytic substance, generally 10–30 percent KOH, which facilitates microscopic examination of the specimen. It is also helpful to add Parker's ink or the lactophenol cotton blue stain, which enables easier demonstration of the fungal elements. A valuable development in this regard involves the use of fluorochromes, such as calcofluor white or analogous products, with affinity for chitin and glucan, which makes the demonstration of fungal elements with a fluorescent microscope relatively simple, not requiring specific expertise (occasionally, nonspecific fluorescence, e.g. cotton fibers, may occur). Stained mounts, such as Gram staining of dermal and nail specimens, or histopathological sections are, generally, not recommended for routine use.

Direct microscopic examination of infected material is expected to reveal the presence of budding yeasts, pseudohyphae, and/or hyphae. The finding is indicative of candidiasis, but does not result in most cases in a definite speciation. The latter can be obtained only by isolation of the fungus in culture and its identification.

Mucosal infections

Specimens from patients with vaginal and oral infections can be collected by swabs (Merz and Roberts 2003) and kept, preferably, in transport medium before being processed in the laboratory. Specimens from oral lesions can also be obtained by scraping.

Processing of the specimen does not generally require treatment with a keratinolytic substance. Both wet and fixed mounts can be used. Wet mounts can be unstained, prepared in saline or water, or stained with lactophenol cotton blue or calcofluor white. Fixed mounts can be stained by Gram, methylene blue or Giemsa. As in the case of skin and nail infections, histopathological sections are not necessary for routine diagnosis of candidal vulvovaginitis or oral candidiasis.

Microscopic examination of specimens from vulvovaginitis or oral candidiasis will demonstrate the presence of budding yeasts, pseudohyphae, and/or hyphae. Demonstration of hyphal elements in direct microscopic mounts is important for the diagnosis, as both the vagina and the mouth are colonized also normally by *Candida* spp., and it is believed that the presence of the hyphal elements noted directly in the clinical specimen, in addition to the yeasts, is an indicator of infection (Figure 4). However, it should be taken into account that *C. glabrata*, a significant non-*albicans* species involved in vaginal infections, does not produce hyphae or pseudohyphae in clinical specimens.

In mucosal infections as well, microscopic examinations serve only as indications of candidiasis, without defining the exact etiology, which can be established only by culture. However, in this context, the significance of the direct examination for diagnosis should be emphasized. Since *Candida* spp. can be found in the mouth and vagina of healthy individuals, positive cultures without direct demonstration of the fungus in the clinical specimen are not always sufficient for diagnosis.

CULTURE

Isolation of *Candida*

The routine medium used for isolation of fungi in culture (Hazen and Howell 2003) from mucocutaneous infections is Sabouraud dextrose agar (SDA) supplemented with antibiotics (chlomphenicol, gentamicin, and/or tetracycline) to prevent bacterial overgrowth. It is also recommended to use an additional isolation medium – SDA to which cycloheximide (Actidione) has been added as well, a medium on which contamination by airborne molds can be limited. It is, however, not recommended to use the latter medium (commercially known as Mycosel or as Mycobiotic agar) as a single isolation medium, since some *Candida* are sensitive to cycloheximide and will not grow.

Candida from mucocutaneous sources are, generally, relatively easily isolated in culture. Cultures can be incubated at 28°C or/and at 37°C, and *Candida* colonies will be apparent within 2–3 days; in some cases growth will be noted already after 24 hours, but may take in others more than 3 days.

Identification and speciation

The description in this section is also relevant to the parallel one in diagnosis of deep-seated *Candida* infections.

It is advisable to obtain pure cultures prior to the identification process and to check by microscopy that the colonies reveal yeasts. Identification of *Candida* and

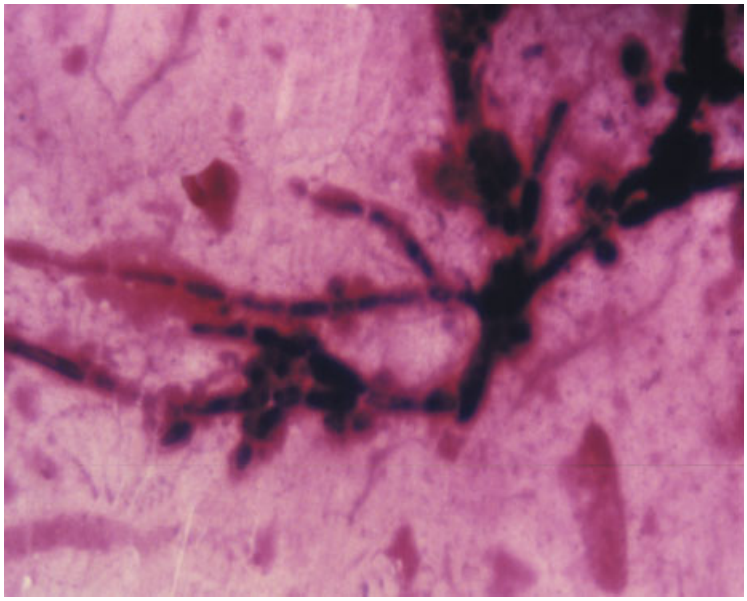

Figure 4 Candida *vaginitis: Gram's stain of clinical specimen*

its speciation is, generally, based on the following categories of criteria: macroscopic/microscopic morphology and physiological/biochemical characteristics; serology for antigenic identification of *Candida* spp. or serotypes can also be applied, although this is not done routinely.

Use of morphology for identification

Macroscopic morphology of *Candida* spp. (Kwon-Chung and Bennett 1992; de Hoog et al. 2000) on routine isolation medium (SDA), is rather similar. *Candida* spp. appear on SDA as smooth, in some species (e.g. *C. krusei*) more dry, cream colonies. Although fine differences between the species can be noted, they are, generally, very difficult to interpret and influenced by subjective judgment, and thus are not believed to be a valid criterion for routine *Candida* speciation.

A number of investigators (Quindos et al. 1992) have undertaken to develop specific media, which would enable, already at the isolation stage, investigators to differentiate, on the basis of macroscopic morphology, the most commonly encountered pathogenic *Candida* spp. The systems were, however, not specific enough or too difficult to standardize for a reliable method. An important development was introduced by Odds and Bernaerts 1994, consisting of the CHROMagar system, which uses chromogenic substances. It is based on the reaction between specific enzymes of the different species and chromogenic substrates, which results in formation of differently colored colonies. This system recommended by the producers for isolation and identification, permits, based on the color of the colonies, fast presumptive identification of *C. albicans*, *C. krusei*, *C. tropicalis* (Figure 5), and others. Of particular notice is *C. dubliniensis*, which grows on this medium in a darker shade of green than *C. albicans*, a characteristic that is helpful in differentiating between the two species.

Microscopic morphology of the culture on SDA isolation medium is also not reliable for species identification. The *Candida* spp. will appear as budding yeasts, and although some differences in the size and shape (oval or more elongated) do exist between the species (see section on Mycological characteristics below), they are too subtle to serve as a reliable, repeatable tool for routine diagnosis.

The commonly used differential medium both for genus identification as well as speciation, is the CMA plate (Dalmau plate) supplemented with Tween 80 or rice agar (de Hoog et al. 2000). Subcultures on CMA plates, made from the SDA isolation medium by furrowing the CMA plates, and incubated for 2–5 days at 28°C, will reveal, upon direct (inverted microscope) or mount microscopic examination, the presence of pseudo- and true hyphae, a characteristic of the genus *Candida* (except for *C. glabrata*, see section on Taxonomic comments, below). In addition, microscopic examination of CMA plates will also reveal species-specific characteristics, such as chlamydospores in *C. albicans* and *C. dubliniensis*, and the typical morphology of the different species (see description under section on Mycological characteristics, below). Both unstained and stained wet or fixed mounts, respectively, can be used to demonstrate the microscopic morphology formed on the CMA plates.

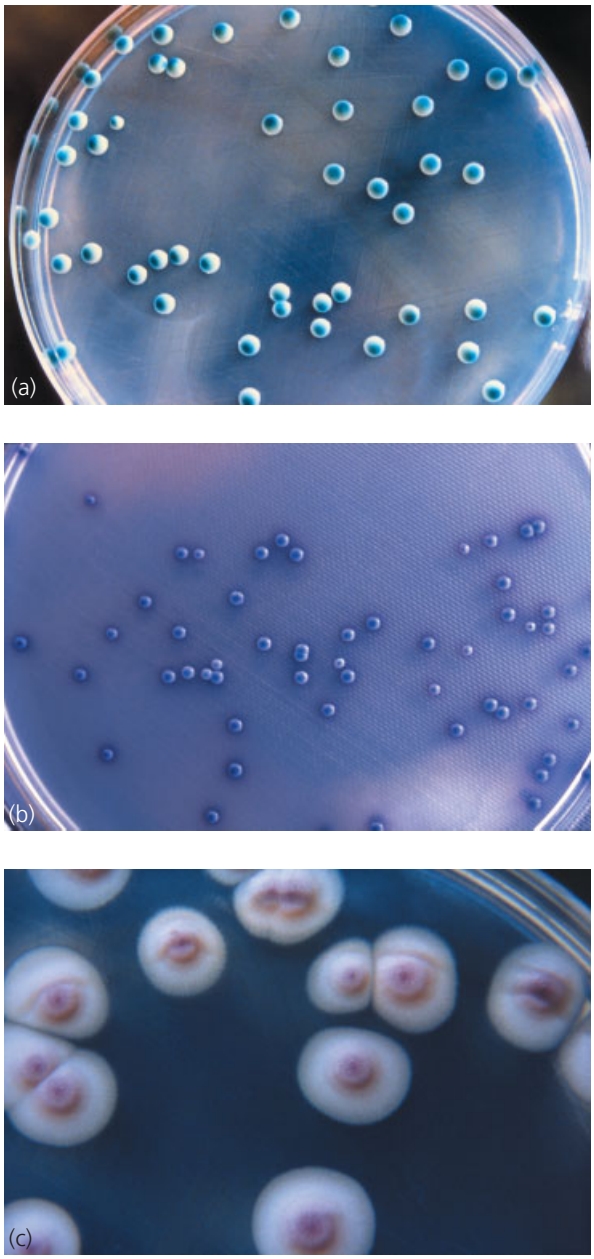

Figure 5 Candida *species on CHROMagar* Candida*:* **(a)** C. albicans*;* **(b)** C. tropicalis*;* **(c)** C. krusei

In the context of morphology, as a basis for species identification, the so-called 'germ tube test' (Merz and Roberts 2003) should be mentioned. The principle of this test is the ability of *C. albicans* or *C. dubliniensis* blastospores to produce, under defined conditions (generally, in serum incubated at 37°C for 2 hours),

germ tubes. The formation of germ tubes and chlamydospores is indicative of these two species and therefore offers reliable and easily performed tests for routine diagnosis.

Physiological/biochemical characterization

The genus *Candida* and the different *Candida* spp., similar to other yeasts, can be characterized by the pattern of utilization of specific carbohydrate and nitrogen substances (see section on Mycological characteristics below). As mentioned earlier, *Candida* spp. can utilize carbohydrates both oxidatively (assimilation) and anaerobically (fermentation). Yeasts possessing the ability to ferment a given carbohydrate do also assimilate that substance, but not necessarily vice versa. Thus, biochemical identification of *Candida* spp. is based primarily on assimilation and fermentation tests.

Various techniques have been developed for assessing the assimilation patterns. The classical Wickerham and Burton (1948) method assessed assimilation by determining the ability of a given yeast isolate to grow in a set of defined minimal liquid media supplemented with different carbohydrates. This method, which, although precise, was laborious and time consuming and therefore not suitable for routine use, was replaced in the clinical laboratory by the auxanographic technique (Hazen and Howell 2003). This technique employs minimal media agar plates on which paper disks impregnated with different carbohydrates are placed, and the growth ability of the yeast around a specific disk is an indication of the yeast's ability to assimilate that carbohydrate. This method is simpler and quicker, and therefore more adapted for routine use. Modifications of this principle are used by various commercial kits, such as the API 20C, API ID32C (Figure 6), Vitek, Minitek, Uni-Yeast-Tek, and others. These commercial systems are easy to use and some are automated. A number of studies focused on comparison of the various methods (Fenn et al. 1994; Riddle et al. 1994). Other methods, such as MicroScan, have also been described (Land et al. 1991; St Germain and Beauchesne 1991).

Fermentation tests are more difficult to perform. The classical tests involved liquid media supplemented with different carbohydrates, a color indicator to assess pH changes to measure acid formation, and a tool to assess gas production (generally an inverted small tube, the Durham tube), a criterion of fermentation. There are several modifications for assessment of gas production, such as use of semisolid media or a wax layer on top of the liquid medium. Most of the commercial kit systems do not use fermentation assays but rely on assimilation tests.

Other identification methods

Unlike diagnosis of mucocutaneous candidiasis, in the deep-seated forms isolation of the fungus may be problematic, its identification, once isolated, is relatively straightforward by the described methods. Nevertheless, additional methodologies for identification have been described.

Candida spp. can also be identified serologically, using specific antisera. A commercially available set of sera (Iatron System), prepared against *Candida* cell wall antigens (see section on Antigenicity below) enables quick species identification of the commonly encountered pathogenic *Candida* spp. by simple slide agglutination. However, serological identification is not used as a standard routine method in clinical laboratories for diagnosis of candidiasis.

Other non-culture identification methods may include molecular techniques (Buchheidt et al. 2000; Alexander 2002; Sullivan and Coleman 2002) such as the use of

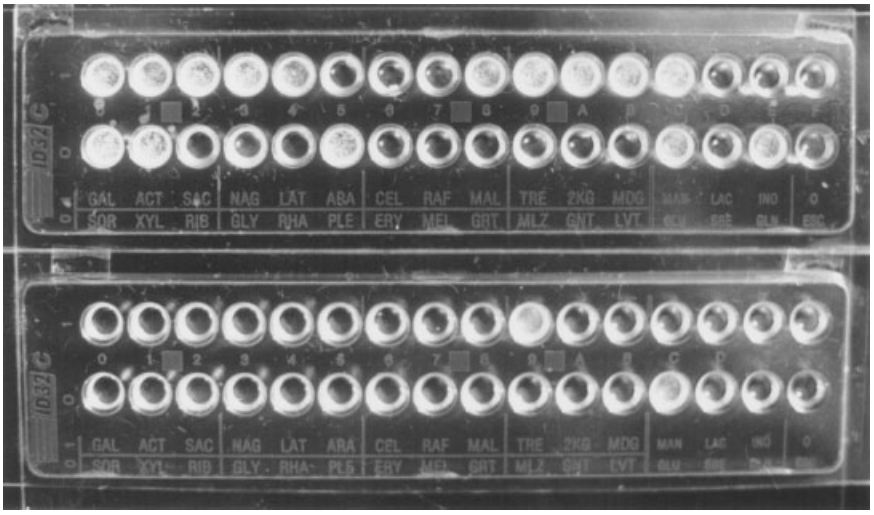

Figure 6 Candida *spp. in API 32C: upper panel,* C. albicans*; lower panel,* C. glabrata

electrophoretic patterns of DNA, RNA profiling, restriction enzyme analysis (Velegraki et al. 1999), and PCR (Niesters et al. 1993; Maiwald et al. 1994; Santos et al. 1994). Common molecular probes used by a number of investigator groups for identification of *Candida* at genus or species level are ribosomal DNA primers, including the large or small rRNA subunits (Haynes and Westerneng 1996). Additional probes described include SAP DNA (Flahaut et al. 1998), the *ERG11* gene involved in ergosterol biosynthesis (Posteraro et al. 2000), and others.

However, once again, these too do not yet, generally, constitute part of routine diagnosis.

Deep-seated candidiasis

Although the basic principles involved in the diagnosis of deep-seated and disseminated candidiasis are similar to those of the mucocutaneous candidiasis, the diagnosis of the deep-seated entities is more difficult and complicated, including various problems at the different steps of the process. While laboratory diagnosis of mucocutaneous candidiasis is based on direct examination of clinical specimen, followed by isolation and identification of *Candida* spp., that of the deep-seated forms involves in addition also use of immunodiagnostic and other noncultural methods.

DIRECT EXAMINATION

Due to the nature of the different clinical forms, collection of clinical specimens may be problematic. In some clinical forms it is difficult to obtain a sample from the infected organ or the specimen can be collected only by invasive methods. In others, such as in the case of samples from the respiratory tract, the demonstration of *Candida* in sputum, a sample which is easily obtainable, poses a problem in interpretation, as *Candida* is part of the oral flora; thus to have meaningful results, it is necessary to obtain samples by the invasive procedures of bronchial lavage or biopsy. Some clinical specimens, such as CSF, may require procedures of concentration due to the possibility of paucity of the pathogen in the clinical sample (Konneman et al. 1997). However, if samples from normally sterile sites are obtained, demonstration in such samples of the presence of yeasts and/or hyphal elements, indicative of *Candida*, is important for the establishment of diagnosis.

Direct demonstration of *Candida* in specimens from deep-seated candidiasis can be done both by wet and fixed mounts, aided by calcofluor white. Tissue biopsies can be prepared and stained by histopathological techniques (Salfelder 1990), using the periodic acid–Schiff (PAS) or the Gomori methamine silver (GMS) stain. An additional method using an immunohistochemical technique was described by Marcilla et al. (1999). These investigators used monoclonal antibodies (3H8), in identification of *C. albicans* (Marcilla et al. 1999).

CULTURE

Isolation of *Candida* species

A basic problem is the difficulty in isolating *Candida* in culture from specimens of deep-seated candidiasis, particularly if the infection is localized in an internal organ. The specimen that is most easily obtainable, which leads to the highest isolation rates, is blood cultures. However, even these are characterized by a relatively high proportion of failure to isolate the fungus (Jones 1990; Pfaller 1992a; Reiss and Morrison 1993). The most recommended methods for blood cultures include the lysis-centrifugation isolator system (Wilson M.L. et al. 1993; Kirkley et al. 1994), which apparently yields the highest rates of positive cultures (Telenti and Roberts 1989), the Bactec radiometric or nonradiometric systems (Yagupsky et al. 1990), and use of biphasic media (Richardson and Carlson 2002). Other specimens from normally sterile sites with lesser rates of positive cultures may include CSF, tissue biopsies, or bronchial washings. Such specimens are inoculated on Sabouraud's agar with antibiotic but without cycloheximide. Growth conditions are similar to those for specimens from mucocutaneous candidiasis. However, it is advisable to wait much longer periods (up to 3 weeks) before a decision is made that a culture is negative.

Identification of *Candida* species

Identification of the *Candida* isolated is done as in the case of mucocutaneous candidiasis. It is based, primarily, on macroscopic and microscopic morphology, and on physiological/biochemical characteristics of the isolates.

Immunodiagnosis

The basis for immunodiagnosis is the patient's immune response to *Candida*, as expressed by presence of antibodies or CMI, and/or presence of microbial antigens in the patient's body fluids. Contrary to the mucocutaneous forms of candidiasis, in which the use of direct examination of the clinical material and culture is quite satisfactory for diagnosis, in the deep-seated entities, these methods, as indicated above, are in many instances not sufficient. Thus, the search for additional approaches, such as the use of immunodiagnostic techniques or other non-culture methods, is warranted, and indeed this led to the development of some diagnostic procedures, primarily in the area of immunodiagnosis (de Repentigny 1992; Reiss et al. 2002).

Immunodiagnosis of candidiasis is based, primarily, on detection of the humoral immune response as expressed in antibody production, and detection of fungal antigens. As a consequence two types of assays are involved in immunodiagnosis:

1 tests for detection of antibodies, primarily in serum
2 tests for detection of the fungal antigen(s) in body fluids, again, primarily in serum.

Tests for detection of antibodies

The classical serology included assays for detection of serum antibodies by various modifications of the agglutination test. However, in view of the ubiquitous and commensal nature of *Candida* spp., antibodies to *Candida* detected by the agglutination technique, which generally represent antimannan antibodies, can be found in healthy individuals or in those with superficial infections (Lew 1989). Thus, this test is not discriminatory enough to be useful in the diagnosis of deep-seated candidiasis. By contrast, tests determining the presence of antibodies raised to *Candida* internal antigens, which, it is assumed, are released into the patient's body fluids, primarily during invasive infection, could be more discriminatory and therefore more useful for diagnosis. In addition, it should be considered that immunocompromised patients, who are the principal candidates at risk to develop systemic infections, have difficulties in mounting an antibody response at detectable levels.

Tests aimed at detecting antibodies to *Candida* antigens released and/or expressed during deep-seated infections, include the gel immunodiffusion (ID) or counter-immunoelectrophoresis (CIE) techniques to detect antibodies to *Candida* cytoplasmic antigens, which are standardized by their protein content (Reiss et al. 2002). Other systems used include the enzyme-linked immunosorbent assay (ELISA) or latex-agglutination (LA) test. Detection of antibodies to defined antigens believed to circulate in body fluids during infection, such as enolase (Mitsutake et al. 1994), heat shock proteins (47 kDa – breakdown of HSP90) Walsh and Chanock (1997), and more recently, specific mannosides (Poulain et al. 2002), although not widely used, has also been evaluated. Low sensitivity is the major problem of using antibody-detection methods in diagnosis, which may be either the result of the use of more discriminatory, less sensitive tests, such as the ID or the poor immune status of a significant proportion of the candidiasis patients.

Although attempts to use techniques that demonstrate the different immunoglobulin types for diagnostic purposes have been described (Fegeller et al. 1990), the presence of IgM anti-*Candida* antibodies as an indicator of a recent infection has, apparently, contrary to other microbial infections, no proven validity. Thus, the differentiation between types of immunoglobulins has limited diagnostic value in candidiasis and, consequently, is generally not carried out for this purpose. Moreover, determination of the specific immunoglobulin type cannot be used effectively for differentiating between the mucocutaneous *Candida* infections and the deep-seated candidiasis forms. The possibility of using antibody detection as a valid diagnostic means is dependent on the specific serological test, which measures the response to a specific candidal antigen rather than a specific immunoglobulin type. It should be emphasized, however, that precipitins detected by the immunodiffusion or counterelectrophoresis tests represent generally IgG antibodies, while other tests, such as hemagglutination, used in some laboratories, can detect the different immunoglobulin types (Fegeller et al. 1990).

Tests for detection of antigens

Detection of *Candida* antigens in body fluids is an important diagnostic tool, particularly in the immunocompromised patients who have difficulties in mounting antibodies at a detectable level (Walsh and Chanock 1997).

Although various techniques have been described (de Bernardis et al. 1993; Reboli 1993), currently the most widely used tests include LA and ELISA (Fujita and Hashimoto 1992). Some of these are commercially available, such as the Cand-Tec or Pastorex LA systems or the lately introduced Platelia system, a modified ELISA method. Antigen is generally detected in serum; however, it can be found also in other body fluids, such as urine (Ferreira et al. 1990). The antigens detected by the different systems include mannan (Pastorex LA), an undefined glycoprotein (Cand-Tec LA), a 47 kDa protein (HSP), enolase (ELISA), and specific mannosides (Platelia) (Walsh and Chanock 1997; Sendid et al. 2002). Generally, the antigen-detection tests are more significant for diagnosis as they detect active infection. Although as a rule they are sensitive tests, they still may not be sensitive enough to detect all the cases of antigenemia, particularly since some of the antigens are cleared quickly from the bloodstream. Another source for false-negative results may come from cases where the infective agent is one of the rarer *Candida* spp., due to the specificity of the antigenic determinants, which are absent or not recognized by the detecting reagent, which is generally an anti-*C. albicans* serum. It has been suggested that concurrent determination of both antigens and antibodies in clinical samples may increase the sensitivity of the diagnosis of systemic candidiasis (Sendid et al. 2002).

CMI as evaluated in vivo by a skin test to measure DTH to candidal antigen, or by in vitro assays such as lymphocyte transformation, are valid tools in assessing the immune competence of the patient, but do not contribute much to diagnosis of candidiasis.

In summary, although the immunodiagnostic techniques are associated with problems of standardization and interpretation, and cannot be used as the sole methods for laboratory diagnosis, they are, nevertheless, a helpful adjunct in the complex diagnosis of deep-seated candidiasis. The use of a combination of antigen-detection and antibody-detection tests is helpful in diagnosing the infection in both the immunocompetent and the non-immunocompetent patient.

Other nonculture methods

Since, as indicated above, in spite of the existence of culture and immunodiagnostic techniques, the diagnosis of deep-seated candidiasis is still problematic, the search for more sensitive and/or more specific methods continued. These included the possibility of detecting non-antigenic fungal metabolites released during infection into the patients' body fluids and, more recently, detection of fungal nucleic acids by sensitive molecular techniques.

Detection of fungal metabolites

Most studies in this area concentrated on detection of arabinitol as a candidal metabolite which is released during infection into the patient's body fluids, and which could possess a diagnostic value (Reiss and Morrison 1993). As arabinitol was first described by Kiehn and Bernard in 1979 as a fungal metabolite detected in the serum of patients with disseminated candidiasis, the techniques to detect this metabolite are in general applicable for serum, although arabinitol can be found also in urine. Arabinitol is released by most of the pathogenic *Candida* species, except *C. krusei* and *C. glabrata* (and not by *Cryptococcus neoformans*).

The techniques to detect arabinitol include the original method by which the metabolite was first detected, gas-liquid chromatography (GLC), and the more recent techniques involving enzymatic-fluorometric measurements (Reiss and Morrison 1993; Switchenko et al. 1994). Moreover, a kit for the latter technique has been described (Tokunaga et al. 1992). Serum arabinitol levels can also be elevated in patients with renal insufficiency and some other clinical conditions. In order to overcome this problem, determination of the serum arabinitol/creatinine ratio is advised.

Another *Candida* metabolite, suggested by Miyazaki et al. (1995) to be useful for diagnosis, is the cell wall component (1→3)-beta-D-glucan for which commercial kits already exist (Hossain et al. 1997). It should, however, be remembered that glucan is found in other fungi as well, therefore its value as a diagnostic tool is debatable (Verweij et al. 1998; Chryssanthou et al. 1999).

Molecular biology techniques

These techniques are based on detection of candidal DNA in patients' body fluids involving the use of specific DNA probes. This approach became more promising as a possible diagnostic tool with the development of DNA amplification techniques, particularly PCR. Recent review articles suggest the usefulness of such methodologies in diagnosis (Reiss et al. 2000; Turin et al. 2000).

Various possible probes have been described, such as the actin gene, the gene encoding cytochrome P450 14-lanosterol demethylase (Burgener Kairuz et al. 1994), the chitin synthetase gene (Jordan 1994), SAP genes (Flahaut et al. 1998), mitochondrial DNA or the candidal DNA repetitive elements (CARE). A widely used probe consists of the rRNA gene complex (Maiwald et al. 1994; Kappe et al. 1998). Some of these probes are species specific while others have wider specificity (Niesters et al. 1993). Although most of the studies aim for fungal detection in serum, some involve other clinical specimens such as urine or tracheal aspirate.

As already indicated in the section on Other identification methods above, such DNA probes can also be used for species identification after these have been isolated in culture. An example of such an approach is a study by Weissman et al. (1995) who used the benomyl resistance gene for *C. albicans* molecular identification.

Successful use of molecular techniques for detection of the fungal DNA in clinical specimens could possibly provide a sensitive means for early diagnosis. However, presently, these techniques are still mostly at the investigatory stage, and do not provide easily applicable methods for routine clinical use.

TREATMENT

Susceptibility testing

Susceptibility testing of fungi to antimycotic drugs, including that of yeasts, was until recently performed only rarely. This was a result of several factors:

- the cases necessitating systemic antifungal treatment were relatively rare
- the number of antifungal drugs was limited
- the incidence of resistance to the drugs was rare
- most importantly, correlation between in vitro and in vivo results was questionable.

These factors have changed: a marked increase in the incidence of mycotic diseases, especially disseminated infections, has been noted, the number of available drugs has increased, and continues to increase, and an innate or acquired resistance of certain yeast species to several drugs has been reported. Thus, collaborative efforts have been initiated, which have culminated in a proposal of a standard for broth dilution susceptibility testing of yeasts (but so far not yeast forms of dimorphic fungi) published as National Committee for Clinical Laboratory Standards (NCCLS) document M27-A2 (National Committee for Clinical Laboratory Standards 2002). The acceptance and use of these standards may, in analogy with similar standards for antibacterial drugs, lead to a better predictive value of in vitro susceptibility testing of antimycotic drugs.

The performance of in vitro fungal susceptibility testing poses considerable difficulties, including the test's procedure (i.e. necessity of adjusting the medium to the

drug, estimation of inoculum size) and particularly their interpretation (Cook et al. 1990; Odds 1993). Several additional problems make reliable antifungal susceptibility testing complicated. Among these are:

- the fact that different morphological cell forms of the same fungus may show different susceptibility to the same drug (azoles seem to be more efficient in inhibiting hyphal forms than blastospores of *C. albicans* (Fromtling 1988; Walsh and Pizzo 1988)
- low water solubility and diffusibility of the drugs as well as their instability (especially polyenes)
- the determination of endpoint minimum inhibitory concentration (MIC) in liquid media, is complicated for some drugs, especially 5-fluorocytosine and the azoles, by the 'trailing' phenomenon: a certain turbidity is noted in the broth above the MIC, indicating a partial growth inhibition (Espinel-Ingroff et al. 1992; Fromtling et al. 1993). To overcome this problem, it has been suggested that it is best to ignore the slight turbidity above the MIC or to use a 1:5 dilution of the drug-free control culture as a reference of 80 percent growth inhibition (Espinel-Ingroff et al. 1992).

Several methods may be implemented in the testing of fungal susceptibility, but only one, the macrodilution technique, has been standardized so far, and is detailed in the NCCLS publication.

Other methods include various microdilution techniques, the results of which, according to preliminary investigations (Espinel-Ingroff et al. 1992, 1995; Tiballi et al. 1995; To et al. 1995), do not diverge significantly from those of the macrodilution method. Tests on solid media include the agar dilution and agar diffusion methods. The diffusion method may be implemented by using drug-impregnated disks or strips, the latter giving an indication of the MIC. This is the principle of the commercially available Etest (Figure 7). In a comparison between results obtained by the Etest and the NCCLS standard method, differences for certain species or specific drugs were shown and the comparison varied, according to the drug tested, between 71 percent and 84 percent (Colombo et al. 1995).

In spite of these advances in standardization of antifungal susceptibility test methods, the most troublesome problem remains the predictive value of the results for therapy. In fact, discrepancies between in vitro results and therapy success still afflict antibacterial susceptibility tests, more than a decade after their standardization, making them useful primarily for the indication of drugs to which the tested microorganism is resistant and thus probably useless for therapeutic purposes. The increase in amphotericin B (Dick et al. 1980; Hadfield et al. 1987) and/or azole-resistant (see section on Prophylaxis below) clinical isolates of yeasts, suggests that indication of possible resistance will presumably also be the primary function of antimycotic susceptibility tests.

Therapy

The therapy of candidiasis, similar to laboratory diagnosis, depends on the type of clinical manifestation and is different for the mucocutaneous forms as opposed to the deep-seated entities. Thus, the topic of therapy will be discussed in the light of the two groups of clinical forms (Richardson and Warnock 1997; Edwards 2000).

THERAPY OF MUCOCUTANEOUS CANDIDIASIS

Patients suffering from cutaneous or mucosal *Candida* infections can in principle be successfully treated topically. The specific drugs include, primarily, the polyene nystatin, and the azoles miconazole, clotrimazole, and ketoconazole (Georgopapadakou and Walsh 1994). The polyene amphotericin B in a formulation for topical administration, and additional azole compounds, such as econazole, sulconazole, and terconazole, have also been used for treatment of mucocutaneous candidiasis (Richardson and Warnock 1997; Edwards 2000; Stevens and Bennett 2000).

Nystatin (Brajtburg et al. 1990) is poorly soluble in water, and the specific formulation may vary according to the clinical entity. Thus, nystatin can be administered as a suspension or gel for treatment of oral candidiasis, and it can also be applied in the form of a cream or suppository, for dermal or vaginal infections, respectively. The duration of treatment may also vary according to the clinical entity. So for nystatin, suppositories of 100 000 units/ml, a 14-day course, is recommended in the treatment of vaginitis (Bennett 1995), while the treatment of oral infection by nystatin suspension of similar concentration may require 2–3 weeks (Richardson and Warnock 1997). For the treatment of cutaneous candidiasis, such as candidal intertrigo or diaper rash, nystatin may be used as topical preparation in combination with anti-inflammatory agents. *Candida* nail infections do not, generally, respond to topical nystatin treatment, although such treatment may be helpful for the accompanying paronychia. Nystatin, as other polyenes, acts on the fungal cytoplasmic membrane through complexing with the ergosterol in the membrane. In the form of topical preparations it is nontoxic and usually devoid of side effects, except for the bitter taste of the suspension used in treatment of oral infection.

The azoles (Fromtling 1988) miconazole, clotrimazole, and ketoconazole can also be used in different formulations, such as lotion, cream, suppository, powder, or spray. They can be applied for the treatment of both cutaneous and mucosal involvement, but are not useful in treating nail infections. The advantage of the azole compounds over nystatin is that the necessary treatment duration is shorter. So a treatment regimen for candidal vulvovaginitis with miconazole cream would require a 7-day use, and for some azoles (e.g. tioconazole) even a

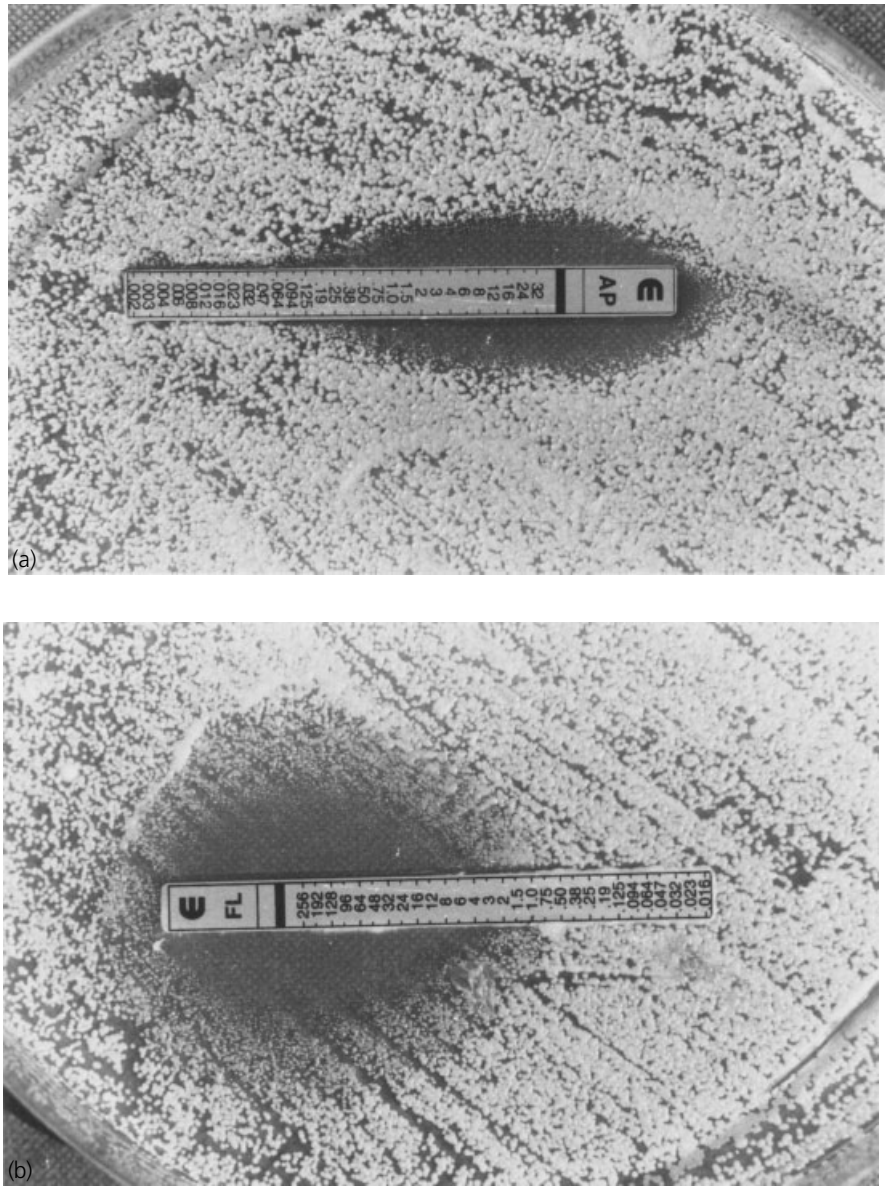

Figure 7 C. albicans *susceptibility testing by Etest:* **(a)** *amphotericin B (AP);* **(b)** *fluconazole (FL). Note the partial inhibition zone around the fluconazole strip.*

single-day treatment could be sufficient in comparison to a 14-day course for nystatin. An additional advantage of the azoles is their broad antifungal spectrum, which permits the use of these drugs even without laboratory confirmation of the candidal etiology of the infection. The azoles, as the polyenes, act on the fungal cytoplasmic membrane, however, through another mechanism – interference in the biosynthesis of ergosterol. Similar to the polyenes, they too, basically lack side effects when used as topical formulations.

Topical treatment will not suffice in nail infections, in CMC patients, in AIDS patients with *Candida* infections, or in cases of recurrent vulvovaginitis. These may require systemic oral therapy. The oral administration of the drugs can replace or be an adjunct to the topical treatment. The major antifungals administered orally for treatment of mucocutaneous *Candida* infections are primarily the triazoles: fluconazole and itraconazole (Bennett 1995). The use of these drugs is currently preferred over that of the oral preparation (tablets) of ketoconazole, as the use of the latter (see below) is associated with more adverse side effects and is not recommended for the treatment of vulvovaginitis (Stevens and Bennett 2000).

Tablets of fluconazole (Zervos and Meunier 1993) have been extensively used for therapy of oral and esophageal candidiasis in AIDS patients (Dupont and Drouhet 1988). Administration of 50–100 or 100–200 mg/day for 2 weeks is effective in the treatment of oral or esophageal candidiasis, respectively. However,

the problem in these patients is the high rate of relapses of the infection. Thus, fluconazole has been used for prolonged periods, as a prophylactic means of preventing relapses of the infection (Just-Nubling et al. 1991). Long-term administration and prophylactic use of fluconazole are also applied for the management of CMC and prevention of recurrences in cases of recurrent vaginal infections, respectively.

Oral use of fluconazole is basically not associated with major side effects (nausea or abdominal pain have been noted in a small percentage of individuals; Bennett 1995). However, prolonged administration of the drug can lead to induction of resistance and was expressed in the appearance of fluconazole-resistant *C. albicans* isolates (Sanguineti et al. 1993; Newman et al. 1994). In addition, fluconazole was also found to be inherently ineffective against certain *Candida* spp., such as *C. krusei* and *C. glabrata* (Hitchcock et al. 1993; Richardson and Warnock 1997). As a consequence, *Candida* speciation seems to be important in regard to therapy and it would be advisable to perform sensitivity testing prior to commencement of treatment.

Itraconazole (Sporanox) has a similar profile of use: AIDS patients, CMC, or vaginitis (Rees and Philips 1992). It has also been applied in treatment of *Candida* nail infections (Hay et al. 1988). As with fluconazole, itraconazole use is apparently devoid of significant adverse reactions. Cross-resistance with fluconazole has been reported (Richardson and Warnock 1997).

As indicated above, the application of the two triazoles is currently preferred over the oral use of ketoconazole (Nizoral), the first azole for systemic administration, due to possible side effects associated with the use of this drug. Administration of ketoconazole can be, albeit rarely, associated with severe hepatotoxicity (Lewis et al. 1984). Ketoconazole use can also interfere with steroid hormone synthesis and be expressed in reduced levels of testosterone (Hanger et al. 1988). Milder, but much more frequent, side effects include nausea and vomiting, at higher doses of the drug. Another problem associated with ketoconazole use is the relatively low absorption of the drug in AIDS patients due to lower gastric acidity in these patients (Richardson and Warnock 1997).

Nystatin can also be used in the form of tablets. Since, as indicated above, nystatin is poorly soluble in water, it is not well absorbed by the GI mucosa. Nystatin tablets have been used as an adjunct to topical treatment in the therapy of recurrent vaginal candidiasis. The rationale of this therapeutic approach is that oral use of nystatin may lead to clearance or reduction of the *Candida* load in the GI tract, and thereby eliminate a possible reservoir for relapse of the vaginal infection.

In CMC patients, who tend to develop relapses, which are explained by their underlying immune defect that renders them susceptible to the infection, an additional therapeutic approach has been investigated. Attempts have been made to potentiate the immunoreactivity of such patients by use of immunomodulatory agents (Kirkpatrick 1993), such as 'transfer factor,' levamisole, or thymosine. The most extensively studied immunomodulator was the transfer factor, a leukocyte extract, which was able to transfer to CMC patients the ability to mount a DTH response, an ability that they lacked.

Additional antimycotic drugs, such as the allylamine terbinafine (Perea et al. 2002), have been shown to have in vitro activity against some *Candida* spp., but have not been widely adopted for clinical use to treat infections with the fungus.

DEEP-SEATED CANDIDIASIS

It is evident that therapy of the deep-seated forms of *Candida* infections requires systemic administration of the antimycotics. The gold standard of antifungals suitable for treatment of systemic mycoses was, and still is, amphotericin B (AMB) (Sarosi 1990). AMB (Fungizone) has a wide antifungal spectrum, it is effective against molds, yeasts, and dimorphic fungi (Bennett 1995). Although, as a rule, resistance to AMB is not a phenomenon restricting the use of this agent, reports on resistant strains of *C. tropicalis* and *C. lusitaniae* are found in the literature (Richardson and Warnock 1997). Resistance of *C. lusitaniae* to AMB may emerge during treatment (Pappagianis et al. 1979; Merz 1984).

AMB is a polyene that acts like other polyenes, through binding to the ergosterol in the fungal cytoplasmic membrane (Georgopapadakou and Walsh 1994), which leads to increased membrane permeability, and subsequently to fungal cell death. As other polyenes, it is water insoluble and consequently not well absorbed from the GI tract and not applicable for oral use, but has to be administered parenterally. The clinically applicable parenteral AMB formulation consists of a lyophilized powder of 50 mg AMB, 41 mg sodium deoxycholate and 25 mg of sodium phosphate, made up in water supplemented with 5 percent of glucose. This formulation is given in the form of a slow (several hours) IV infusion (Edwards 2000).

The dose and duration of AMB treatment of deep-seated candidiasis is dependent upon the specific clinical entity, and the category of patients involved: non-immunosuppressed, granulocytopenic, or otherwise immunosuppressed. Nevertheless, a protocol has been adopted, which in general terms can be outlined as involving treatment with 0.5–1 mg/kg/day of AMB for a duration of 6–10 weeks. In view of the possible side effects associated with AMB therapy, it is recommended to initiate the treatment at a low dose, and monitor the patient's response before dose increase.

Treatment with AMB is associated with considerable side effects. These may include acute reactions and cumulative effects. The acute reactions may include, fever, chills, hypotension, nausea, and vomiting. These

side effects can be ameliorated or prevented by some supportive measures, such as use of steroids and/or Ibuprofen. The major risk of AMB treatment is its cumulative effect – the nephrotoxicity (Sabra and Branch 1990). AMB therapy causes renal impairment in most patients. Thus, AMB treatment requires careful monitoring of renal functions. Although the renal impairment can be reversible several months after cessation of treatment, irreversible damage does also occur. Other, less common, not immediate, effects may include anemia.

The problem of AMB therapy associated with its significant toxicity seems to be overcome to some extent by newer formulations involving AMB–lipid complexes (Janoff 1990; Meunier 1989; Fielding 1991). Three major formulations of this type are currently available: AMB with dimyristoyl phosphatidyl choline and dimyristoyl phosphatidyl glycerol (ABLC, Abelcet), AMB with cholesterol sulfate (ABCD, Amphocil), and a liposomal AMB preparation (AmBisome) (Chopra et al. 1991). The AMB–lipid complexes are characterized by lower nephrotoxicity. They can, therefore, be administered at significantly higher doses (5 mg/kg/day), doses which are not tolerated with the traditional AMB formulation. The major drawback of these formulations is their current extremely high cost, which hampers their use on a wider scale. It should be added, in this context, that trials with mixtures of AMB and Intralipid (Chavanet et al. 1992; Caillot et al. 1993; Nath et al. 1999), which significantly lower the cost of the treatment, have been carried out.

Disseminated candidiasis can also be treated by a combination of AMB and 5-fluorocytosine (5-FC) (Polak 1987). 5-FC (flucytosine, Ancobon) is a fluorinated pyrimidine, which acts as an antimetabolite (Diasio et al. 1978). Following deamination it converts into 5-fluorouracil (5-FU), which is incorporated into RNA resulting, subsequently, in impaired protein synthesis. Additional conversion of 5-FU into 5-fluorodeoxyuridilic acid, which can act as an inhibitor of thymidilate synthetase, may result in inhibition of DNA synthesis.

5-FC is water soluble and absorbed quite well by the GI mucosa following oral administration (tablets, capsules); it is usually given at a dose of 150 mg/kg/day (Bennett 1995). It is also well distributed in the body fluids, reaching significant levels in CSF. In patients with no underlying major renal dysfunction, 5-FC treatment leads rarely to side effects, which may include nausea, vomiting, and diarrhea. However, more serious side effects, such as leukopenia, thrombocytopenia, and hepatotoxicity, are also known, particularly among patients with underlying renal or hematological impairments. In such patients careful monitoring is required. The major disadvantage of 5-FC treatment is the frequent occurrence of resistant strains during the course of treatment, and even the presence of primary resistant strains (Stiller et al. 1982) being a recognized phenomenon. Thus, laboratory assessment of the fungal isolate's sensitivity to 5-FC prior to commencement and during the course of treatment, as well as careful monitoring of serum levels of the drug, is recommended.

5-FC is generally not administered as a single therapeutic agent, but rather given in combination with AMB. It is believed that the combined treatment may enable the use of lower AMB doses, thereby reducing possible side effects, without compromising its therapeutic efficacy. The combined treatment is particularly recommended in *Candida* meningitis, due to the high passage of 5-FC through the blood–brain barrier.

The triazoles fluconazole and itraconazole have been considered as possible alternatives to AMB, or additional agents in the treatment of deep-seated candidiasis. The triazoles act as the other azoles (imidazoles) by interfering in the biosynthesis of ergosterol, through inhibition of lanosterol demethylation, involving binding to cytochrome P450 enzymes. The advantage of the triazoles over the imidazoles is that they affect less the synthesis of human sterols (Hanger et al. 1988) and, therefore, are less associated with side effects. As a consequence, use of triazoles would seem preferable over the imidazole ketoconazole, which is also suitable for systemic (oral) use and could be considered for treatment of deep-seated candidiasis. (Kauffman et al. 1991, 1993; Meunier et al. 1992).

Fluconazole is active against most *Candida* spp. However, resistant *C. albicans* strains have been isolated, primarily from AIDS patients under prolonged fluconazole treatment (Richardson and Warnock 1997). Of clinical significance is also the phenomenon of certain species, such as *C. krusei* and *C. glabrata*, which reveal initial insensitivity to the drug. Epidemiologic data point to an increase in incidence of systemic candidiasis due to these species (Hazen 1995; Nguyen et al. 1996; Krcmery and Barnes 2002), which may possibly be the result of selective pressure of fluconazole use.

Fluconazole is available in two forms, tablets (50, 100, 200 mg) for oral use and a formulation for IV use. Fluconazole is quite soluble and well absorbed from the GI tract after oral administration (Bennett 1995). It is also well distributed in the human body sites, including the CNS; its level in the CSF can reach 70 percent of that in the serum. Its use is rarely followed by serious side effects, but nausea, vomiting, and diarrhea have been recorded in a small percentage of treated individuals.

Fluconazole dose and treatment duration depend on the specific clinical entity and take into consideration the patient involved. Generally, doses of 200–400 mg/day (higher doses of up to 800 mg/day have also been reported) for 6–8 weeks are used. Of the deep-seated *Candida* infections, fluconazole has been used extensively and successfully in treatment of esophagitis; it has also been applied in treatment of endocarditis, hepatosplenic candidiasis or in candidemia of non-immunosupressed patients (Bennett 1995).

Itraconazole can be used orally in the form of capsules and, more recently, as solution and parenterally

by IV administration. It is less well absorbed from the GI tract than fluconazole, and crosses the blood–brain barrier less well. Cross-resistance with fluconazole does, apparently, exist, and reports on resistance of *C. glabrata* have been published (Dermoumi 1994). Itraconazole has been used in treatment of *Candida* esophagitis. In view of the recent introduction of the IV formulation, its role in other deep-seated *Candida* infections is not yet clear.

It is noteworthy that voriconazole, the most novel licensed triazole, has activity against non-*albicans* species resistant to fluconazole, such as *C. glabrata* and *C. krusei*.

Another more recent antifungal drug approved for use in treatment of candidemia is the lipopeptide (echinocandin) caspofungin. Caspofungin is a semisynthetic compound acting as a glucan synthesis inhibitor. It is administered intravenously and is the first antifungal drug active on the fungal cell wall. Combinations of caspofungin and azole are currently being evaluated by in vitro studies (Roling et al. 2002).

At present, most clinicians feel that AMB therapy, particularly that using AMB–lipid complexes, is still preferable for treatment of systemic candidiasis in severely ill immunosuppressed patients.

Immunotherapy as an adjunct to antimicrobial treatment has also been undertaken. This included the use of cytokines, such as for example, granulocyte colony-stimulating factor (G-CSF). However, as these attempts were sporadic and limited, it is difficult to draw conclusions as to the efficacy of this approach (Stevens 1998; Edwards 2000).

Prophylaxis

Vaccination is considered a most effective measure for prevention of microbial diseases. The last decade has seen several attempts to prevent *Candida* infections in humans by employing anti-*Candida* antibodies (Rigg et al. 2001). However, this approach is still experimental and has not yet reached the stage of a commercial vaccine. Thus, other alternatives, primarily the use of antifungals on a prophylactic basis in patients at risk, seem to be a reasonable approach. Since one of the principal aims in the earlier studies was to reduce the fungal load, particularly in the GI tract, which is a major source for *Candida*, and thereby reduce the risk of infection, nystatin was used in these attempts.

Later studies, with few exceptions (Damjanovic et al. 1993), focused on the triazoles (Thunnissen et al. 1991; Wingard et al. 1991, 1993; Goodman et al. 1992; Cesaro et al. 1993; Winston et al. 1993; Chandrasekar and Gatny 1994), mostly fluconazole (Thunnissen et al. 1991). The population groups in whom prophylactic attempts have been undertaken include, primarily, leukemia patients (Winston et al. 1993), neutropenic individuals (Cesaro et al. 1993), bone marrow transplants (Wingard et al. 1991), and neonates in intensive care units (Damjanovic et al. 1993), all of which are considered at high risk for the development of candidiasis.

These studies indicated that prophylactic use of antifungals could reduce *Candida* colonization (Chandraseker and Gatny) or GI carriage (Damjanovic et al. 1993), and possibly also infection (Goodman et al. 1992). However, they also pointed to the important observation that the possible preventive effect was mostly noted in regard to *C. albicans* and not to the non-*albicans* species: *C. krusei* (Wingard et al. 1991; Goodman et al. 1992; Winston et al. 1993), *C. guilliermondii*, *C. parapsilosis* (Cesaro et al. 1993), and *C. glabrata* (Wingard et al. 1993; Chandrasekar and Gatny 1994). Thus, an increase in candidiasis due to non-*albicans* species has been noted in at-risk patients (Hazen 1995; Nguyen et al. 1996; Krcmery and Barnes 2002).

It is noteworthy that, while the use of nystatin would have an effect solely in preventing *Candida* infections, the use of triazoles is expected to have a broader spectrum of activity. While this approach still continues, studies comparing the efficacy and toxicity of different compounds have been published (Walsh 2002). Walsh and colleagues compared voriconazole and liposomal AMB in neutropenic patients and reached the conclusion that 'voriconazole is a suitable alternative to amphotericin B preparations for empirical therapy in patients with neutropenia.' Another study by Wolff et al. (2000), which compared fluconazole with low-dose AMB in bone marrow transplants, found both antifungals have been effective in prophylaxis, with better tolerance of the triazole.

A more recent study of Bow et al. (2002) undertook a meta-analysis including several azoles and AMB, reaching the conclusion that antifungal prophylaxis reduced morbidity and mortality caused by fungi.

It has recently been indicated (Sobel 2003) that the echinocandins, being characterized by their action on the fungal cell wall, show promise for prophylactic use in high-risk patients.

In addition, other possible prophylactic measures that have been suggested include a more cautious use of venous catheters, a risk factor for candidemia (Nucci 2003), use of immunomodulatory means to boost the immune system such as granulocyte transfusions (Van Burik 2003) or cytokines (e.g. G-CSF) (Rodriguez-Adrian et al. 1998; Stevens 1998).

Serious infections caused by uncommon yeasts

JANINE R. MAENZA AND WILLIAM G. MERZ

Spectrum of clinical disease	1	Conclusions	10
Microbiology	7	References	10

There are more than 500 species in almost 50 genera of yeast, or yeast-like organisms, that have been described in the world's literature. This vegetative morphological form must convey advantages to the organism, since yeast have arisen in several different branches in the evolution of fungi. This is exemplified by many ascomycetous and basidiomycetous yeast genera.

Members of the asexual genus *Candida*, and one of the sexual basidiomycetous *Cryptococcus* spp., *Cryptococcus neoformans*, cause most serious human yeast infections. In addition, however, there are less common yeast genera that may also cause human infection. These include members of the genera *Blastoschizomyces*, *Hansenula*, *Malassezia*, *Rhodotorula*, *Saccharomyces*, *Sporobolomyces*, *Trichosporon*, and *Ustilago*.

Most members of these genera have caused fungemia with or without organ invasion in immunocompromised patient populations. Although uncommon, these infections are an important clinical entity as they are often difficult to treat, due to both the compromised nature of the patient and the refractoriness of the organisms to standard antifungal regimens.

SPECTRUM OF CLINICAL DISEASE

Most of these organisms are associated with environmental sources and are less frequently encountered as colonizers of humans. The major exception is the genus *Malassezia*, which is a very common component of the normal skin flora of humans and many animal species. The other genera are not usual components of our normal flora, but may be found as transient colonizers. Persistent colonization, when it occurs, is seen more often in hospitalized or immunocompromised patients. Colonization may then serve as a precursor to infection.

Given the relative rarity of these infections most reported information is in the form of case reports and case series. Derived from these reports, Table 1 summarizes the types of infections caused by individual genera. The most common infection is fungemia, but there are also reports of solid organ involvement with most of these yeast. The host characteristics of patient populations who are more at risk for infection are described in Table 2. As apparent from this table, most of these infections occur in immunocompromised patient populations.

Blastoschizomyces

Blastoschizomyces capitatus, formerly included in the genus *Trichosporon*, is known to be an environmental organism. Nevertheless, an observational report that represents the largest collected series of infection with this organism failed to reveal a common environmental exposure (Martino et al. 1990b). In this study, 20 patients with evidence of *B. capitatus* colonization or infection were identified, yet no environmental source was found, nor was the isolation of *B. capitatus* from environmental cultures related to cases of colonization or infection (Martino et al. 1990b). There was also no evidence for a common source of transmission through food, equipment, or personnel. Given the rarity of clinical disease with *B. capitatus*, risk factors for the development of infection are not clearly defined, but notably the single case series (Martino et al. 1990b) and multiple case reports (Martino et al. 1990b; Girmenia et al. 1991;

Table 1 *Types/sites of infection*[a]

Type or site of infection	*Blastoschizomyces*	*Hansenula*	*Malassezia*	*Rhodotorula*	*Saccharomyces*	*Sporobolomyces*	*Trichosporon*	*Ustilago*

+ Reported only in isolated case reports.
++ Reported in larger case series or observational studies.
a) *Hanseniospora* is not included because it has not been shown to cause infection (see section on Microbiology below).

D'Antonio et al. 1994; Pagano et al. 1996) describe the development of disease in patients with hematological malignancies, the vast majority of whom were neutropenic at the time of development of infection.

Twelve of the 20 patients in Martino's case series had *B. capitatus* infection, rather than simply colonization. Each of these 12 presented with fever in the setting of fungemia or solid organ invasion. Sites of solid organ involvement included lung, liver, spleen, kidney, central nervous system, and heart (Martino et al. 1990b). Lung involvement was manifest by productive cough and radiographic studies showing infiltrates (which appeared to be mycetomas in some) (Martino et al. 1990a, b). Hepatic, renal, and/or splenic involvement appeared as focal, nodular lesions seen by imaging studies, and laboratory evaluation demonstrating abnormal liver function tests (Martino et al. 1990a). Central nervous system involvement was manifest clinically by neurological deficits and radiographically by the appearance of focal intracerebral lesions. Myocarditis and endocarditis were both diagnosed at autopsy in one patient with symptomatic heart failure (Martino et al. 1990a). In contrast to the patients with infection, those with transient colonization in this series had *B. capitatus* in stool or urine cultures with no evidence for invasive disease.

In additional reports, other types of infection have included osteomyelitis and diskitis, which developed after *B. capitatus* fungemia (D'Antonio et al. 1994), and

meningitis (Girmenia et al. 1991). Both these infections were in children who had received bone marrow transplants for acute leukemia. An adult leukemia patient with hepatosplenic *B. capitatus* infection (DeMaio and Colman 2000) and a pediatric leukemia patient with *B. capitatus* osteomyelitis (Cheung et al. 1999) have also been reported.

Diagnosis of *B. capitatus* infection is usually made by culture of blood, or other affected body site. Biopsy may be needed to show invasive disease; e.g. in patients with pulmonary symptoms and positive sputum cultures, lung biopsy may be used to show histological evidence of invasion.

Treatment of disseminated *B. capitatus* infection requires systemic antifungal therapy. Fluconazole and flucytosine have good in vitro activity (Vendetti et al. 1991). In clinical practice, amphotericin B with or without flucytosine has frequently been used (Martino et al. 1990a, b; D'Antonio et al. 1994). Fluconazole was used as treatment in the case of meningitis: symptoms resolved and the organism was eradicated from the cerebrospinal fluid. Three months after fluconazole was discontinued, however, the patient was found on autopsy to have persistent evidence of meningeal invasion with *B. capitatus* (Girmenia et al. 1991). After a course of amphotericin B, itraconazole was used as continuation treatment in the child with osteomyelitis (D'Antonio et al. 1994). A crucial aspect of treatment is also likely to be resolution of neutropenia; one case report describes a lack of response to antifungal therapy until the patient was treated with granulocyte-macrophage colony-stimulating factor (GM-CSF) (Pagano et al. 1996), another describes the effective use of interferon-gamma (IFN-γ) for hepatosplenic infection after the failure of amphotericin B alone (DeMaio and Colman 2000).

Hansenula

The more commonly recognized *Hansenula* species, *Hansenula anomala*, is an environmental colonizer that may be isolated from organic substances including vegetables, fruit, and soil. Less common is *Hansenula polymorpha* which may also be found colonizing environmental sources (Lodder 1970; McGinnis et al. 1980).

The first reported case of human infection with *H. anomala* was of a child with interstitial pneumonia (Csillag et al. 1953). Subsequent cases include additional patients with pulmonary involvement (Csillag and Brandstein 1954; Kane et al. 2002), neonatal ventriculitis (Murphy et al. 1986), endocarditis (Nohinek et al. 1987), and urinary tract infection (Qadri et al. 1988). Most reported cases have described fungemia without end-organ involvement (Milstoc and Siddiqui 1986; Murphy et al. 1986; Klein et al. 1988; Yamada et al. 1995; Ma et al. 2000; Wong et al. 2000). *H. anomala* has also been reported as the actual etiologic agent in cases of oral 'candidiasis' (Cameron et al. 1993).

Risk factors for *H. anomala* infection appear to be similar to those described for other opportunistic fungal infections. These include central venous catheters, use of broad-spectrum antibacterials and hyperalimentation, immunosuppression/neutropenia, and surgery (Klein et al. 1988; Thuler et al. 1997).

Diagnosis of *Hansenula* infection is usually by isolation of the organism in culture of the infected site. Treatment of systemic *H. anomala* infection should include removal of the central venous catheter, if one is present, and use of a systemic antifungal agent. The optimal agent and dose have not been established. Parenteral amphotericin B is commonly used, and in vitro studies demonstrate susceptibility to this agent (Klein et al. 1988; Goss et al. 1994). There is, however, one report of amphotericin B failure, with subsequent successful sterilization of blood cultures by use of ketoconazole (Wong et al. 2000). Lipid complex amphotericin was successfully used to treat *H. anomala* in one patient with pneumonia, fungemia, and acute renal failure (Kane et al. 2002). The utility of fluconazole is unclear since there are reports of its successful use (Hirasaki et al. 1992; Goss et al. 1994; Yamada et al. 1995), but also reported instances of in vitro fluconazole resistance (Yamada et al. 1995), clinical failure of fluconazole treatment (Yamada et al. 1995), of the development of *H. anomala* infection in a patient already taking fluconazole for treatment of a *Candida* urinary tract infection (Alter and Farley 1994), and of breakthrough fungemia with *H. anomala* despite fluconazole prophylaxis (Krcmery et al. 1998).

There is only one clearly documented case of tissue infection with *H. polymorpha*: a child with chronic granulomatous disease developed hilar lymphadenopathy (McGinnis et al. 1980). *H. polymorpha* was recovered from cultures of hilar, posterior mediastinal, and paratracheal lymph nodes. The patient was successfully treated with amphotericin B.

Malassezia

Among the *Malassezia* species, *Malassezia furfur* is the most commonly identified cause of human infection. Infections with *Malassezia pachydermatis* are less common. There are a few case reports of *Malassezia sympodialis* infection. The most common types of *Malassezia* infection are superficial cutaneous and folliculitis (see Superficial diseases caused by *Malassezia* species).

The major type of serious infection caused by *M. furfur* is central venous catheter-related fungemia. Neonates, especially those receiving lipid infusions (Sizun et al. 1994) and immunosuppressed patients, both children and adults (Barber et al. 1993; Morrison and Weisdorf 2000) are the patient populations most at risk for infection. Early reports suggested that *M. furfur* fungemia was almost always associated with the use of

parenteral lipid infusions, but later reports describe the infection in patients without this risk factor (Myers et al. 1992; Barber et al. 1993). The clinical findings of *M. furfur* fungemia are nonspecific and the same as those seen with other types of bloodstream infection: fever, leukocytosis, thrombocytopenia (Barber et al. 1993).

In many reports of *M. furfur* infection, the organism is isolated only from blood cultures drawn through the central venous catheter (i.e. peripheral blood cultures are negative), and solid organ involvement is absent. There are, however, cases reported of pneumonia (Redline and Dahms 1981; Richet et al. 1989), peritonitis (Wallace et al. 1979; Gidding et al. 1989), and an intracardiac mass (Schleman et al. 2000) caused by *M. furfur*.

Although venous catheter colonization clearly occurs, all *M. furfur* fungemia should be treated, since prediction of catheter colonization versus true systemic infection is not possible. As for the other uncommon yeast infections, treatment of serious *M. furfur* infections is not standardized, but usually involves removal of the central venous catheter and use of systemic antifungal therapy (Marcon and Powell 1992; Morrison and Weisdorf 2000). Intravenous amphotericin B is the most commonly utilized antifungal agent.

M. sympodialis is a human colonizer and is felt to be a pathogen despite a paucity of reports of human infection. The strongest evidence for a pathogenic role comes from the isolation of the organism from the scalp of a patient with the acquired immunodeficiency syndrome (AIDS) with a focal skin infection (Simmons and Gueho 1990), as a central venous catheter-related infection in a surgical-oncology patient (Kikuchi et al. 2001), and as the cause of malignant otitis externa in a man with diabetes mellitus (Chai et al. 2000). It is also possible that *M. sympodialis* is under-recognized as a cause of infection since most laboratories do not distinguish it from *M. furfur*.

M. pachydermatis is also recognized as a cause of human infection. Essentially all reported cases are of fungemia in neonates (Marcon and Powell 1992; Lautenbach et al. 1998; Chryssanthou et al. 2001). There is also at least one reported occurrence of fungemia in an immunosupressed adult with a central venous catheter. As with *M. furfur* and other yeasts, central venous catheters and the administration of intravenous lipids may be risk factors for infection (Welbel et al. 1994). Removal of the venous catheter and administration of amphotericin B are both components of treatment of this infection as well. There are also reports of susceptibility to fluconazole and itraconazole, and resistance to flucytosine (Chryssanthou et al. 2001).

Rhodotorula

Rhodotorula species have been isolated from many environmental sources including soil, water, fruit juice, milk products, shower curtains, toothbrushes, and fiberoptic bronchoscopy equipment (Kwon-Chung and Bennet 1992; Whitlock et al. 1992; Warren and Hazen 1995). Infections due to the genus are rare, but are most frequently due to *Rhodotorula rubra*. Infections due to *Rhodotorula minuta* (Gregory and Haller 1992; Goldani et al. 1995; Pinna et al. 2001; Cutrona et al. 2002) and *Rhodotorula glutinis* (Pien et al. 1980; Casolari et al. 1992; Gaytan-Martinez et al. 2000; Dorey et al. 2002; Hsueh et al. 2003) have also been reported.

As with the other genera, the most commonly described infection due to *Rhodotorula* is fungemia. There are also reports of endocarditis (Naveh et al. 1975), meningitis (Pore and Chen 1976; Ahmed et al. 1998; Huttova et al. 1998), ventriculitis (Donald and Sharp 1988), peritonitis (Eisenberg et al. 1983; Wong et al. 1988; Pennington et al. 1995), and eye infections (Casolari et al. 1992; Gregory and Haller 1992; Guerra et al. 1992; Muralidhar and Sulthana 1995).

Rhodotorula fungemia most commonly occurs in patients with central venous catheters (Kiehn et al. 1992; Alliot et al. 2000; Kiraz 2000). Risk factors for the development of this infection are the same as those described for other opportunistic fungal bloodstream infections (immunosuppression, neutropenia, broad-spectrum antibacterials, hyperalimentation, burns, and surgery) (Marinová et al. 1994), but may also include endocarditis (Pien et al. 1980). The clinical presentation of *Rhodotorula* fungemia is nonspecific, with findings that may be seen in any bloodstream infection: fever, chills, tachycardia, and hypotension (Pien et al. 1980). Of note, many reports of *Rhodotorula* fungemia describe bloodstream infections that are polymicrobial.

Since *Rhodotorula* infections other than fungemia are rare, few general conclusions can be drawn about their clinical presentation. *Rhodotorula* peritonitis has only been reported in patients undergoing peritoneal dialysis and is notable for a propensity to lead to peritoneal fibrosis (Donald and Sharp 1988). Eye infections due to *Rhodotorula* species have included chronic postoperative endophthalmitis (caused by *R. minuta*) (Gregory and Haller 1992), keratitis (*R. glutinis*) (Casolari et al. 1992; Guerra et al. 1992), and dacryocystitis (Muralidhar and Sulthana 1995).

When deciding on treatment, it must be recognized that *Rhodotorula* may be an environmental contaminant. In one series where *Rhodotorula* was isolated from blood cultures (lysis centrifugation method) in 36 patients, only 23 were felt to have clinically significant fungemia. In the remainder there was only one colony of yeast isolated on one culture plate, and no clinical evidence of infection (Kiehn et al. 1992). In vitro susceptibility testing has shown that *Rhodotorula* is sensitive to flucytosine, moderately sensitive to amphotericin B, miconazole, ketoconazole, and itraconazole, and often resistant to fluconazole (Kiehn et al. 1992; Marinová et al. 1994; Galan-Sanchez et al. 1999). Treat-

ment of fungemia has historically included systemic antifungal treatment and/or removal of a central venous catheter. Current recommendations for treatment are not standardized, but usually involve removal of the central catheter when feasible (Pien et al. 1980) and the use of amphotericin B at doses of 0.7 mg/kg/day (Kiehn et al. 1992). It may also be reasonable to add flucytosine to this regimen. *Rhodotorula* peritonitis has often been treated with intraperitoneal amphotericin B (Eisenberg et al. 1983; Wong et al. 1988), but this may exacerbate the risk of peritoneal fibrosis, and therefore intravenous amphotericin B may be preferable.

Saccharomyces

Saccharomyces cerevisiae is commonly known as baker's yeast or brewer's yeast, and is used in baking bread or making beer. Human colonization may occur at any mucosal surface, but happens more commonly in patients with underlying illnesses (Greer and Gemoets 1943; Kiehn et al. 1980; Aucott et al. 1990). A recent case series showed that increasing length of hospitalization was also a risk factor for greater likelihood of colonization with *S. cerevisae* (Salonen et al. 2000).

Clinical infections most commonly occur at the sites of mucosal colonization (thrush, esophagitis, vulvovaginitis), but invasive infections have also been reported. Overall, these infections occur in patients with significantly compromised immune systems. *S. cerevisiae* is thus a weak pathogen at best, but one that can clearly cause invasive opportunistic disease in an immunocompromised host. The specific underlying diseases associated with invasive *S. cerevisiae* infection include malignancy (Aucott et al. 1990), AIDS (Sethi and Mandell 1988; Doyle et al. 1990), myelodysplastic syndromes (Aucott et al. 1990; Oriol et al. 1993), burns (Eschette and West 1980), and rheumatoid arthritis (Feld et al. 1982). Clinical characteristics that may also be associated with disease are those described for other opportunistic fungal infections [invasive procedures/surgery (Dougherty and Simmons 1982; Chertow et al. 1991), hyperalimentation (Aucott et al. 1990), broad-spectrum antibacterial therapy (Aucott et al. 1990), and the presence of central venous catheters (Cimolai et al. 1987)]. Isolated fungemia is most common, but solid organ involvement may occur. Documented sites of deep infection include the lungs (Aucott et al. 1990), liver (Aucott et al. 1990), and joints (Feld et al. 1982). Empyema (Chertow et al. 1991) and peritonitis (Dougherty and Simmons 1982) have also been reported. There are also several case reports of *S. cerevisiae* fungemia after therapeutic use of *Saccharomyces boulardii* (Cesaro et al. 2000; Perapoch et al. 2000)

Clinical features of *S. cerevisiae* infection are not specific to the organism, but instead are determined by the site of infection. Blood cultures are diagnostic of fungemia, but since the organism is a common colonizer of mucosal surfaces, histological confirmation of tissue invasion is often necessary in order to diagnose solid organ involvement (Aucott et al. 1990).

Successful treatment of invasive *S. cerevisiae* infection with oral azoles has been noted in case reports (Dougherty and Simmons 1982; Cairoli et al. 1995), but there are also reports of azole-resistant *S. cerevisiae* (Salonen et al. 2000), and, in general, fungemia and/or solid-organ infection should be treated with parenteral amphotericin B.

OTHER *SACCHAROMYCES* SPECIES

S. boulardii is a *Saccharomyces* species, not usually considered a pathogen, that has been used in the treatment of bacterial diarrhea. In this setting, there have been reported cases of fungemia due to *S. boulardii* (Zunic et al. 1991; Pletincx et al. 1995; Hennequin et al. 2000; Rijnders et al. 2000; Lherm et al. 2002; Riquelme et al. 2003). Treatment should involve discontinuation of *S. boulardii* and institution of antifungal therapy.

Sporobolomyces

Sporobolomyces is usually recovered only from soil, occasionally from other environmental sources (leaves, bark, grasses, fruit) and rarely as a cause of human infection. Case reports describe one instance of mycetoma in which *Sporobolomyces roseus* was isolated (Janke 1954), one patient with dermatitis due to *Sporobolomyces holsaticus* (Bergman and Kauffman 1984), and several infections that appear due to *Sporobolomyces salmonicolor*. The reports of *S. salmonicolor* in which the organism is acting as pathogen have included one report of a positive culture from a removed nasal polyp (Dunnette et al. 1986), lymphadenitis (Plazas et al. 1994) and bone marrow involvement in AIDS patients (Morris et al. 1991), and a prosthetic cranioplasty infection (Morrow 1994). In addition, there is one reported case of extrinsic allergic alveolitis being caused by *Sporobolomyces* spp. in a veterinary student who developed fever, cough, and dyspnea when exposed to straw from which the organism was isolated: the patient had serum precipitans against *Sporobolomyces* and a positive intradermal skin test (Cockcroft et al. 1983). Furthermore, there is a description of an outbreak of asthma after a thunderstorm during which time there had been an increase in the number of *Sporobolomyces* spores in the air, suggesting the organism may have contributed to this event (Packe and Ayres 1985).

Given the rarity of clinical infection due to *Sporobolomyces* spp., there is clearly no standard therapy. Treatment which has been used successfully includes amphotericin B (Morrow 1994), amphotericin B followed by ketoconazole (Morris et al. 1991), and amphotericin B followed by fluconazole (Plazas et al. 1994).

Trichosporon

Trichosporon beigelii is a part of normal soil flora, and is occasionally found as colonizer of the oropharynx, skin, and nails. The organism was initially noted to cause superficial infections of the hair shaft (see Superficial diseases caused by *Malassezia* species), then recognized as a pathogen capable of causing invasive disease (Watson and Kallichurum 1970). Most reported cases of disseminated infection have been in patients who are immunosuppressed in the setting of hematologic or solid organ malignancy, or solid organ transplantation (Sarfati et al. 1983; Murray-Leisure et al. 1986; Ness et al. 1989; Mirimoto et al. 1994; Tashiro et al. 1994). A series from Japan described 43 patients identified with disseminated *T. beigelii* infection: 37 (86 percent) of these patients had an underlying hematological malignancy. The majority of these patients (26 of 43) had been profoundly neutropenic (ANC $<100/mm^3$) prior to the development of infection (Tashiro et al. 1994). Notably, nearly all the patients in this series without a hematological malignancy were receiving systemic corticosteroids. Other populations in which *T. beigelii* fungemia has been described include premature infants (Giacoia 1992; Fisher et al. 1993; Singh et al. 1999), burn patients (Hajjeh and Blumberg 1995), and patients with the human immunodeficiency virus (HIV) infection (Anuradha et al. 2000; Girija et al. 2001).

Both a colonized gastrointestinal tract and central venous catheters are considered potential portals of entry for this infection. Pulmonary involvement is, however, the most common site of end-organ disease (Tashiro et al. 1995). Chest x-rays may show diffuse interstitial infiltrates or patchy reticulonodular involvement (Hoy et al. 1986; Tashiro et al. 1995). Signs and symptoms are similar to those of other fungal pneumonias in immunosuppressed patients: persistent fever in the face of antibacterial therapy associated with dyspnea, cough, and bloody sputum production (Tashiro et al. 1995). Other organs that are less commonly involved in disseminated *T. beigelii* infection include the brain (Watson and Kallichurum 1970), eyes (Sheikh et al. 1974), heart (Sidarous et al. 1994), liver (Haupt et al. 1983), spleen (Bhansali et al. 1986), bone (Goodman et al. 2002), and peritoneum (Anuradha et al. 2000). It is also important to note, however, that *T. beigelii* funguria may be a benign finding, not associated with invasive infection, in renal transplant patients (Lussier et al. 2000). There is also one report of a breast implant infection with *T. beigelii* in an immunocompetent patient (Reddy et al. 2002).

Cutaneous findings in association with deep *T. beigelii* infection have included macules, papules, vesicopustules, and nodules which may be localized to the extremities or found dispersed over the entire body (Piérard et al. 1992; Hsiao et al. 1994). Clinically, these lesions may appear similar to those seen in disseminated candidiasis. Cellulitis may also occur (Libertin et al. 1983). Skin biopsy with culture and/or histological studies may be necessary to clarify the diagnosis.

Disseminated trichosporon infection is often diagnosed by blood cultures. In the face of end-organ disease, diagnosis may also be made by biopsy of the affected site with culture or histopathological studies. Histology most frequently shows both yeast forms and hyphal elements that are larger than those seen in *Candida* infections (up to 10 μm). An example is illustrated by renal involvement in a neutropenic patient with leukemia (Figure 1). Arthrospores may be seen in some infections. Another distinguishing histological feature is that *T. beigelii* is commonly found arranged in a radial pattern (Tashiro et al. 1994). Immunoperoxidase staining has also been used as a diagnostic modality since discrimination between *Candida* and *T. beigelii* in tissue sections may occasionally be difficult (Tashiro et al. 1994). Of note, serum from patients with disseminated *T. beigelii* infection may show cross-reactivity with the latex agglutination test commonly used to diagnose infection with *Cryptococcus neoformans*.

Although intravenous amphotericin B is used as standard treatment of disseminated trichosporonosis, there are many reports of therapeutic failures (Walsh et al. 1990; Fisher et al. 1993; Tashiro et al. 1994). In one series, nine of 11 patients with trichosporon fungemia died of systemic fungal infection despite therapy with amphotericin B (Krcmery et al. 1999). In vitro susceptibility testing has demonstrated that although *T. beigelii* is inhibited by standard concentrations of amphotericin B, the levels required for the lethal effects on the organism are much higher. For example, using seven clinical isolates of *T. beigelii*, Walsh demonstrated that the organism was inhibited by standard concentrations of amphotericin B (< 2.0 μg/ml). With both a macrodilution technique and timed kill studies, however, they found that the majority of strains were not killed unless

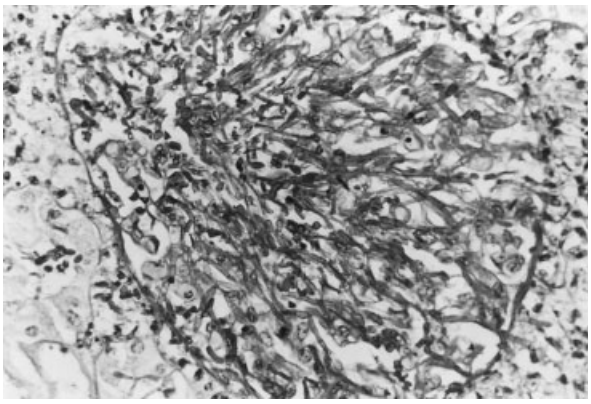

Figure 1 *Kidney involvement with* T. beigelii *in a neutropenic patient with leukemia (periodic acid–Schiff (PAS) 300×)*

extremely high concentrations of amphotericin B (> 20 μg/ml) were used (Walsh et al. 1990). Thus, amphotericin B is a static agent at attainable concentrations, making treatment difficult in patients who lack neutrophils to combat the infection. Other therapeutic options which have been considered include: the use of high-dose amphotericin B, combination treatment with amphotericin B and flucytosine or rifampin or fluconazole, liposomal amphotericin B, and systemic azoles (Walsh et al. 1990; Anaissie et al. 1992; Hajjeh and Blumberg 1995; Canales et al. 1998; Cawley et al. 2000). Although there are in vitro data showing synergism between terbinafine and azoles against *T. beigelii* (Ryder 1999), to our knowledge there are no clinical reports of its use.

OTHER *TRICHOSPORON* SPP.

In the past, species other than *T. beigelii* were only rarely reported as the cause of clinical infections. The taxonomy of this genus has now been redefined (see section on Microbiology below). *Trichosporon capitatum*, *Trichosporon fermentans*, and *Trichosporon penicillatum* are now classified as *Blastoschizomyces* and *Geotrichum* species. In addition, newly defined species, including *Trichosporon asahii*, *Trichosporon inkin*, *Trichosporon louberi*, *Trichosporon mucoides*, and *Trichosporon pullulans*, are being reported with increased frequency. There may be an impact on human infection since virulence may vary among these species. There are several case reports of invasive *T. pullulans* infection: one of pneumonia and the remainder of intravascular catheter-related fungemia in neutropenic patients (Shigehara et al. 1991; Kunová et al. 1995; Krcmery et al. 1999). Patients with *T. pullulans* fungemia have developed the infection while receiving ketoconazole and itraconazole antifungal prophylaxis (Kunová et al. 1995, 1996). There are also reports of bone marrow transplant patients receiving fluconazole prophylaxis who have nevertheless acquired serious *Trichosporon* infections (Moretti-Branchini et al. 2001). In one patient *T. asahii* caused fatal fungemia, despite the use of amphotericin. In the other, *T. inkin* caused a vascular catheter infection. One case report also describes a *T. inkin* lung abscess (Piwoz et al. 2000). Table 3 summarizes these sites of infection, and other case reports of infection with trichosporon species other than *T. beigelii* (Abliz et al. 2002; Fournier et al. 2002; Gokahmetoglu et al. 2002; Meyer et al. 2002; Crowther et al. 2003; Nettles et al. 2003; Padhye et al. 2003).

Ustilago

Ustilago species are known as pathogens of corn and other grains. In corn, they are also known to induce tumor formation (Banuett 1995). *Ustilago maydis* has been described as an allergen causing asthma and *Ustilago esculenta* has been reported as a cause of hypersensitivity pneumonitis (Yoshida et al. 1996). There is one report of a central venous catheter infection with *Ustilago*. This infection occurred in a man with a chronic indwelling venous catheter who visited a farm frequently. The organism was isolated from the catheter, and subsequently from blood cultures 3 days after the catheter was removed. The infection resolved without use of an antifungal agent, but susceptibility testing showed that amphotericin B, fluconazole, and itraconazole should each have been effective (Patel et al. 1995).

MICROBIOLOGY

In order to understand the phylogenetic position of a yeast species, the sexual, teleomorph, stage needs to be demonstrated. This may be difficult since some species are heterothallic, requiring two genetically different, but compatible, strains for sexual reproduction to occur. In addition, there are data that suggest that some fungi, including yeast species, have lost their ability to reproduce sexually.

For this discussion, the less common yeast will be divided by their known or implied teleomorph classification. The ascomycetous yeast include members of the genera *Hansenula*, *Haseniospora*, and *Saccharomyces*. The basidiomycetous yeast include species of *Blastoschizomyces*, *Malassezia*, *Rhodotorula*, *Sporobolomyces*, *Trichosporon*, and *Ustilago*. In the absence of asci/ascospore or basidia/basidiospore production, other characteristics can be used to define their phylogenetic positions. This separation may be very important, as there are data that some cell wall active antifungals may not inhibit cell wall synthesis of all classes of fungi. Simple tests that can be performed in a clinical laboratory include testing for urease activity and determining staining with DBB. Methods such as DNA reassociation

Table 3 *Sites of* Trichosporon *infection*

Site	*T. asahii*	*T. inkin*	*T. louberi*	*T. mucoides*	*T. pullulans*
Pulmonary	–	+	–	–	+
Bloodstream/disseminated	+	+	–	+	+
Renal/urinary	–	–	+	–	–
Peritoneum	–	+	–	–	–
Liver/spleen	+	–	–	–	–

Table 4 *Characteristics of ascomycetous (non-*Candida*) yeast recovered from clinical specimens*

Characteristic	*Hansenula* spp.	*Hanseniospora* spp.	*Saccharomyces* spp.
Budding	Multilateral with narrow attachments	Bipolar, elongated daughter cells	Multilateral
Hyphae	± Pseudohyphae, rarely true	Absent to extensive	± Pseudohyphae
Ascospores	Hat-shaped	Spherical to hat-shaped	Spherical
Temperature	± 37°C	± 37°C	± 37°C
Fermentation	± (species dependent)	+	+
Nitrate utilization	+	–	–

studies, G/C content and rRNA/DNA sequencing are also available in research laboratories to elucidate phylogenetic relationships.

Ascomycetous yeast

Ascomycetous yeasts that have been recovered from clinical specimens, and may lead to human infection, include species of *Hansenula*, *Haseniospora*, and *Saccharomyces*. Characteristics of these yeasts are shown in Table 4. All three genera are urease negative and DBB negative.

HANSENULA

Although there are at least 30 species of *Hansenula* that have been described, the two most frequently encountered are *H. anomala* (*Candida pelliculosa*) and *H. polymorpha*. Key characteristics are the lack of urease, presence of hat-shaped ascospores, ability to utilize nitrate, compatible carbohydrate assimilation patterns and both species are fermenters. (Kurtzman 1984; Warren and Hazen 1995). Clinically relevant *Hansenula* spp. are shown in Table 5.

HANSENIOSPORA

There are at least eight recognized species of *Hanseniospora*, but only three may be encountered in clinical specimens (*Hanseniospora uvarum*, *Hanseniospora valbyensis*, and *Hanseniospora guilliermondii*) (Table 6). To date, none is known to have caused actual infection. Identification is based on ascospore production, lack of urease and nitrate utilization, fermentation, and compatible carbohydrate assimilation patterns (Smith 1984).

SACCHAROMYCES

Pseudohyphae or chains of budding yeast cells may be present. Asci and ascospores (usually four) are seen in many strains. There are seven species within this genus of which *S. cerevisiae* is the one associated with humans. Identification of this species can be made by carbohydrate assimilation patterns and microscopic morphology (ascospores can be seen in approximately 60 percent of strains). The genus cannot utilize nitrates, and all species are capable of fermenting sugars (Yarrow 1984; Warren and Hazen 1995).

Basidiomycetous yeast

Members of six genera of basidiomycetous yeast have been reported to cause human infection. Characteristics of these yeasts are shown in Table 7. Most are positive for urease activity and DBB staining.

BLASTOSCHIZOMYCES

Blastoschizomyces is a basidiomycetous genus with a single species, *B. capitatus*. This species was originally classified in the genus *Trichosporon*, which shares many similarities. Identification of *B. capitatus* is established by morphology with the production of true hyphae and annelloconidia, lack of urease activity, growth up to 42–45°C, growth in the presence of cycloheximide, and compatible carbohydrate assimilation patterns (Salkin et al. 1985; Warren and Hazen 1995).

MALASSEZIA

All *Malassezia* species but one (*M. pachydermatis*) require exogenous fatty acids for growth. Identification to the level of genus may be made based on the char-

Table 5 *Clinically relevant* Hansenula *species*

Characteristic	*H. anomala*	*H. polymorpha*
Ascospores	1–4, hat-shaped	1–4, less hat-shaped, more hemispherical
Hyphae	Pseudohyphae may be produced, but no true hyphae	Neither pseudo- or true hyphae
Growth at 37°C	±	+
Specific carbohydrate assimilation patterns	+	+
Fermentation	+	+

Table 6 *Clinically relevant* Hanseniospora *species*

Characteristic	*H. uvarum*	*H. valbyensis*	*H. guilliermondii*
Ascospores	1–2, spherical	2, rarely 4, hat- to helmet-shaped	1–4, mostly 4, hat- to helmet-shaped
Hyphae	Pseudohyphae, ± extensive	Pseudohyphae, ± extensive	Pseudohyphae, ± extensive
Growth at 37°C	–	–	+
Specific carbohydrate assimilation patterns	+	+	+
Fermentation	+	+	+

acteristics in Table 7; more detailed information for speciation is provided in Superficial diseases caused by *Malassezia* species).

RHODOTORULA

Rhodotorula is a common yeast in environments associated with water. A key characteristic is the production of carotenoid pigments that convey an orange/pink color to the colonies. No *Rhodotorula* species produce true hyphae. Identification is based on the pigment, urease activity, nonfermenter, lack of utilization of inositol, and nitrate utilization. Some strains may produce capsular-type material. There at least eight species; some are the anamorph stage of the genus *Rhodosporidium*. Of the eight, *R. rubra*, *R. glutinis*, and *R. minuta* are encountered. They can be speciated by the characteristics noted in Table 8 (Fell et al. 1984; Warren and Hazen 1995).

SPOROBOLOMYCES

Sporobolomyces is another pigmented, basidiomycetous yeast genus. Key characteristics of the genus include the production of carotenoid pigments, presence of budding, true hyphae, forcibly discharged ballistospores, presence of urease activity, and the inability to ferment carbohydrates. There are at least seven species and perhaps the anamorph stage of *Sporidiobolus*. Of the seven species, *S. holsaticus*, *S. roseus*, and *S. salmonicolor* have been recovered from clinical specimens. Separation of these two species is based on morphology, temperature optima, and carbohydrate assimilation patterns. See Table 9 (Fell and Statzell Tallman 1984).

TRICHOSPORON

Trichosporon is a genus characterized by the production of septate hyphae, abundant arthrospores, budding cells (that may be difficult to discern), and an inability to ferment carbohydrates. Most also express urease activity. *T. beigelii* (or *T. cutaneum*, which is the correct taxonomic name) is the most common species in this genus associated with humans, as both a colonizer and as a pathogen. Three species associated with humans have been re-evaluated and transferred to other genera; *T. capitatum* has been transferred to the genus *Blastoschizomyces*, and *T. penicillatum* and *T. fermentans* have been transferred to the genus *Geotrichum*. Most other species are environmental and rarely associated with humans.

In the past, the asexual genus *Trichosporon* encompassed a very heterogenous group of species that were the anamorph stages of both ascomyceterous and basidiomycetous fungi. Over the last 20 years, this genus has received significant taxonomic evaluation and revision. This genus now is considered a basidiomycetous yeast genus based on cell wall structure, positive DBB staining, septal pore morphology, urease production, similar rRNA sequences, and similarity of a complex polysaccharide antigen cross-reactive with the capsular antigen of *Cryptococcus neoformans* (Kreger-van Rij 1984).

Table 7 *Characteristics of basidiomycetous (non-cryptococccal) yeast recovered from clinical specimens*

Characteristic	*Blastoschizomyces*	*Malassezia*	*Rhodotorula*	*Sporobolomyces*	*Trichospsoron*	*Ustilago*
Colony pigmentation	–	–	+	+	–	–
Budding	May be present (anellospores)	Unipolar	Multilateral	Multilateral	May be difficult to observe	Present
Hyphae	True	±	Usually absent	True and pseudo	True	–
Other spores	Arthrospores	–	–	± ballistospores	Arthrospores	Absent
Temperature	up to 45°C	37°C	± 37°C	± 37°C	± 37°C	–
Lipid-dependent	No	All, except *M. pachydermatis*[a]	No	No	No	No
Urease	–	+	+	+	Most positive	No
Fermenter	No	No	No	No	No	

a) *M. pachydermatis* is lipophilic, but not lipid-dependent.

Table 8 *Clinically relevant* Rhodotorula *species*

Characteristic	*R. rubra*	*R. glutinis*	*R. minuta*
Hyphae	Rudimentary, pseudohyphae may be produced	Usually absent, pseudohyphae if present	Absent
Growth at 37°C	±	±	±
Nitrate utilization	–	+	–
Specific carbohydrate assimilation patterns	+	+	+

Table 9 *Clinically relevant* Sporobolomyces *species*

Characteristic	*S. holsaticus*	*S. roseus*	*S. salmonicolor*
Hyphae	Extensive true hyphae, rare pseudohyphae	Absent	Absent–present, pseudo or true
Ballistospores	Usually produced	usually abundant	Usually produced
Growth at 37°C	–	–	±
Nitrate utilization	+	+	+
Specific carbohydrate assimilation patterns	+	+	+

Identification of *Trichosporon* spp., especially *T. cutaneum* (*beigelii*), currently requires morphological and biochemical studies (for details, see Superficial diseases caused by *Malassezia* species). Morphologically, abundant true hyphae are produced within 24–72 hours that give rise to arthrospores which are initially rectangular in shape. Blastospore production is usually more difficult to observe. They may be produced along the true hyphae, or in chains from pseudohyphae, or they may even bud off from the arthrospores. Most species including *T. cutaneum* (*beigelii*) are urease positive, do not ferment carbohydrates, but assimilate many carbohydrates. Assimilation patterns are commonly used for identification of members of this genus.

Gueho et al. 1992 have performed an extensive evaluation of 101 strains representing the full range of species recovered from humans, animals, and environmental sources. Characteristics used for assessment included morphology, ultrastructure morphology, physiological parameters, ubiquinone systems, G/C content of DNA, DNA/DNA reassociation percentages, and partial sequences of 26S rRNA. A total of 19 taxa were delineated within this genus using data from all of the characteristics. Members of six of the 19 taxa were associated with humans: *T. asahii*, *T. asteroides*, *T. cutaneum*, *T. mucoides*, *T. ovoides*, and *T. inken*. Fortunately, speciation within this genus can be accomplished using temperature studies, assimilation reactions, and cylcoheximide susceptibility or resistance. DNA-related studies by Sugita et al. 1995 confirmed the studies of Gueho et al. 1992. Human infections caused by *T. cutaneum* (*beigelii*) were caused by at least four different DNA-based species. When DNA association percentages of 10 clinical strains of *Trichosporon* were determined, seven of the eight isolates recovered from blood or urine specimens were *T. asahii* and one was *T. ovoides*. Of the two strains recovered from superficial infections, one was *T. cutaneum* and one was *T. montevideense*. Clinical studies with identification to the levels of these taxa will be needed to determine whether there are differences in virulence or treatment associated with any of these new taxa.

USTILAGO

Ustilago is a yeast-like phase of an important plant disease called the smuts. They are recognized by their elongated budding cells.

CONCLUSIONS

With growing populations of immunocompromised patients, it is likely that the uncommon yeast described in this chapter and other species will become ever more important. Further changes in epidemiology and spectrum of disease may be noted in upcoming years with the increasing use of extended-spectrum azoles and cell wall acting echinocandins. Accurate recognition of the causative organisms of specific infections, continued reporting of efficacy of different therapeutic options, and the use of standardized in vitro susceptibility testing should allow ongoing refinements in the treatment of the patients affected by such infections.

Clinical presentation	9		

Cryptococcus neoformans is an encapsulated heterobasidiomycetous fungus that has become a major human pathogen and a common infection in certain immunocompromised hosts (Perfect and Casadevall 2002). Cryptococcosis, the disease resulting from infection with *C. neoformans*, varies from a localized skin lesion or asymptomatic colonization of the respiratory tree to a widely disseminated life-threatening infection, which may infect all organs of the body. However, *C. neoformans* has a special propensity for invading the central nervous system and cryptococcal meningoencephalitis is the primary clinical presentation for the life-threatening stage of this infection.

HISTORY

Historically, human cryptococcosis was first described in 1894 when Busse and Buschke independently reported on the same case of a 31-year-old woman with a history of enlarged lymphatic glands who had developed a large ulcer over her tibia (Buschke 1895). Busse observed yeast-like forms in histological sections of the lesion and he was able to culture the yeast, which he initially referred to as *Saccharomyces*. The patient died and was found at autopsy to have multiple abscesses in the lungs, spleen, kidneys, bones, and skin. No mention of symptoms attributable to the central nervous system (CNS) or examination of the CNS was made in this patient. The first isolation of *Cryptococcus* from the environment was reported in 1894 when Sanfelice isolated the yeast from peaches and named it *Saccharomyces neoformans* (Sanfelice 1894). A few more reports of isolation of this fungus from humans and animals occurred, and then in 1901 Vuillemin renamed the yeast *Cryptococcus hominis* to distinguish it from *Saccharomyces* spp. because it did not form ascospores (Vuillemin 1901).

The first published case of cryptococcal meningitis was diagnosed in a 29-year-old woman with leptomeningeal involvement described by Verse in 1914 (Verse 1914). Two cases of meningitis were then described in 1916 by Stoddard and Cutler and, on complete pathological inspection of the CNS tissue obtained postmortem, these investigators observed yeast forms with surrounding areas of clearing in the tissue (Stoddard and Cutler 1916). This finding was initially misinterpreted as evidence of tissue histolysis and they renamed the yeast *Torula histolytica*, and the syndrome was referred to clinically as torulosis. There was confusion over the fact that one yeast was now considered under three different genera (*Saccharomyces*, *Cryptococcus*, and *Torula*) until 1935 when Benham published a comprehensive study of yeasts that contained 22 cryptococcal strains including the original Busse–Buschke strain (Benham 1935). Based on morphology, fermentation, and serological studies, she concluded that all the cryptococcal isolates should be considered as one species and she designated the name as *Cryptococcus hominis*. Unfortunately, the term 'torulosis' continued to be used for another quarter of a century despite Benham's proposals to call the

disease cryptococcosis. *C. neoformans* is now considered the most valid name based on priority since Sanfelice first proposed the species name in 1894, and for the last 40 years *C. neoformans* has been the name used to designate the yeast causing cryptococcosis. In 1976, Kwon-Chung discovered and characterized the sexual stage of this basidiomycete and the teleomorph was named *Filobasidiella neoformans* (Kwon-Chung 1976). Finally, the entire genome of *C. neoformans* was sequenced in 2003.

Cryptococcosis was considered a clinical rarity in the early 1900s. In Littman and Zimmerman's textbook on cryptococcosis, published in 1956, they had found just over 300 cases of cryptococcosis in the world's medical literature before 1955 (Littman and Zimmerman 1956). The number of cases of cryptococcosis has dramatically increased since the 1950s. This increase results partly from greater awareness of *C. neoformans* as a pathogen, but mostly the increase parallels the ever-enlarging population of immunocompromised individuals as a result of aggressive chemotherapies, organ transplantation, and the acquired immunodeficiency syndrome (AIDS). In many medical centers throughout the world, *C. neoformans* is the most commonly identified pathogen obtained from cerebrospinal fluid (CSF) cultures in adults.

MYCOLOGY

There are 19 species within the genus *Cryptococcus*, and they have been found on every continent and in or on a variety of terrains and animals. All members of the genus are nonfermentative, assimilate inositol, and generally produce urease. Although occasional cases of other cryptococci such as *Cryptococcus laurentii* and *Cryptococcus albidus* are alleged to cause human infections (Lynch et al. 1981; Horowitz et al. 1993), *C. neoformans* should be considered the only cryptococcal species that is routinely pathogenic for humans. Isolation of other cryptococcal species from clinical specimens should generally require both culture and histological proof of tissue invasion before attributing disease to them.

Serotypes

C. neoformans can be subclassified into four serotypes and three varieties. The serotypes are based on variation in capsular epitopes and thus different capsular agglutination reactions (Ikeda et al. 1982). These serotypes are designated as A, B, C, and D (Evans 1950; Evans and Kessel 1951; Vogel 1966) and there are diploid or hybrid strains designated AD. There are specific polyclonal or monoclonal antibodies that can recognize each of the serotypes. Prior to the molecular age of *C. neoformans*, serotype A and D strains were included under var. *neoformans* but today are separated into two varieties, *neoformans* and *grubii*, and the serotype B and C strains were considered under var. *gattii*. The varieties differ in their biochemical properties (Table 1) such as the ability of var. *gattii* strains to use glycine or proline as sole sources of nitrogen whereas var. *neoformans*/*grubii* strains cannot (Dufait et al. 1987). The var. *gattii* strains are also resistant to the chemical canavanine, whereas var. *neoformans*/*grubii* strains are usually sensitive (Polacheck and Kwon-Chung 1986). The ability to utilize glycine and the resistance to canavanine were exploited to distinguish var. *gattii* from var. *neoformans*/*grubii* strains. A medium called CGB contains canavanine (C) and has glycine (G) as the sole nitrogen and carbon source. When variety *gattii* strains are grown on CGB agar, glycine is metabolized and results in the formation of ammonia which alkalinizes the medium and converts the bromothyol blue (B). The variety *neoformans*/*grubii* strains usually cannot metabolize glycine and those rare isolates that can are almost always inhibited by the canavanine that is also present in the medium. Urease activity is another difference between the two varieties in that var. *gattii* urease is sensitive to dicationic chelating agents such as EDTA, but var. *neoformans*/*grubii* urease is resistant. This difference can be important if isolates are grown on media containing EDTA and then subjected to a rapid urease test. The test can be falsely negative for var. *gattii* strains. There have only been rare reported cases of *C. neoformans* infections with urease-negative strains (Ruane et al. 1988; Bava et al. 1993). With recent DNA typing methods and other genetic features, some mycologists have even proposed that var. *gattii* be actually reclassified as a separate species and named *Cryptococcus bacillospora*.

The only reliable differences in morphology between these varieties are in the teleomorph stage (see section on Life cycle and genetics below). There is no credible way to distinguish the yeast forms of the varieties based on morphology. However, var. *gattii* basidiospores tend to appear more bacilliform or rod-shaped oval when compared with var. *neoformans*/*grubii* basidiospores.

Table 1 *Comparison of* C. neoformans *var.* neoformans *with var.* gattii

Variety	Serotypes	Canavanine resistance	Glycine as sole nitrogen source?	Shape of basidiospores
neoformans	A and D	No	No	Round
gattii	B and C	Yes	Yes	Elliptical

There are significant differences in the ecology and epidemiology between the two varieties and these will be further discussed in those sections.

Through a variety of genetic analyses, it has been demonstrated that the serotype A and D strains have significantly diverged from each other. It is estimated from population genetic studies that these serotypes have separated from each other over 18 million years ago (Xu et al. 2002). To account for significant genetic diversity, there is the proposal to separate these serotypes into two varieties (Franzot et al. 1999) which we use in this chapter. Serotype A was proposed to be named var. *grubii* and serotype D would be var. *neoformans*. The varietal status for the serotype AD strains is uncertain, but there is evidence that most of these strains represent diploids and/or hybrids. These findings show that these varieties still have the ability to mate with each other. As previously mentioned, Kwon-Chung identified the sexual stages of *C. neoformans* and these findings allowed for the completion of the fungal life cycle. Furthermore, *C. neoformans* can also be divided into eight distinct molecular genotypes: VN 1–4 for serotype A and VG 1–4 for serotypes B and C (Meyer et al. 2003). Serotype D isolates have proven more difficult to cluster into distinct genotypes.

Life cycle and genetics

The life cycle of *C. neoformans* involves two distinct forms: asexual and sexual. First, in the asexual stage *C. neoformans* exists as yeast cells and reproduces by simple budding (Figure 1). These haploid, unicellular yeasts are the only forms of *C. neoformans* that have been recovered from the environment and human infections. These yeast-like forms exist in one of two mating types, 'a' or 'alpha', and when yeasts of opposite mating type are combined under certain conditions they can undergo conjugation to produce the perfect (sexual) state (Kwon-Chung 1975). Generally, these matings occur in the laboratory on nonenriched media such as V8 juice or hay-infusion agar, and temperatures must be held under 37°C. In fact, room temperature, minimal water exposure, and environmental P_{CO_2} concentrations are the best conditions for mating to occur. These observations suggest that there are regulatory controls for mating that respond to certain environmental signals such as nitrogen starvation and temperature. Recent work has begun to dissect the genes and pathways in *C. neoformans* that control this bipolar mating system (Hull and Heitman 2002). The mating type loci for several serotypes have been sequenced and annotated. Genes for pheromones and their receptors have been identified and the signaling networks that control mating have been determined and studied.

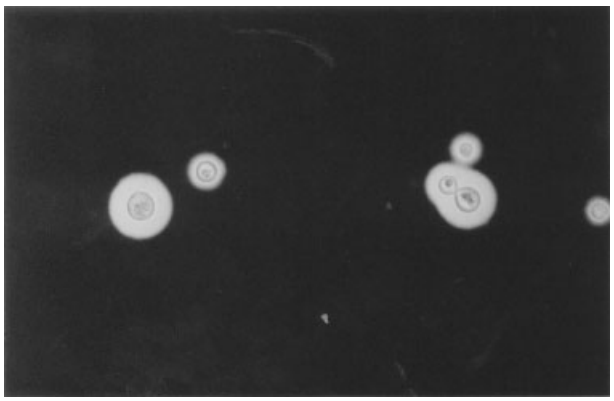

Figure 1 *India ink preparation of the yeast forms of* C. neoformans. *The India ink particles serve to outline the large polysaccharide capsules of the yeasts, making them appear as clear areas surrounding the yeasts. Note the one mother yeast cell with the attached daughter cell that is budding.*

Conjugation between the 'a' and 'alpha' mating strains results in the formation of the teleomorph (sexual) stage which consists of dikaryotic hyphae that bear true clamp connections (Figure 2). Some of these hyphae develop specialized terminal structures called basidia, and the formation of these structures is the basis of classifying the teleomorphs in the phylum Basidiomycota. Furthermore, careful study of the hyphae, basidia, and spore chains showed them to be similar to members of the genus *Filobasidium*. Meiosis occurs at the terminal portion of the basidium and uninucleate basidiospores are formed. These basidiospores bud off at the ends of the basidia in a basipetal fashion to form four chains of spores. These spores are initially unencapsulated but can quickly develop capsules when released from the basidia onto agar and begin budding as yeasts and thus complete the sexual life cycle. The perfect state of *C. neoformans* has been observed only in the laboratory and never conclusively shown to occur in nature. In fact, it is unknown to what extent, if any, sexual reproduction presently occurs in nature. Some investigators have hypothesized that the basidiospores produced by the perfect state may be the infectious propagule for humans because they are ideally suited in size (1–2 μm) for inhalation into the alveoli (Ajanee et al. 1996). Strains of the appropriate mating types of serotype A or D can mate with each other (A × A, A × D or D × D), and the resulting teleomorph is called *Filobasidiella neoformans* var. *neoformans* (Kwon-Chung 1975). Likewise, serotype B and C strains can mate with each other (B × B, B × C or C × C), and the teleomorphs in this case are called *Filobasidiella neoformans* var. *bacillispora* (Kwon-Chung 1975). The teleomorphs of the two varieties can be distinguished on morphological grounds on the basis of their basidiospores. The var. *neoformans* produces chains of spherical basidiospores, whereas the var. *bacillispora* produces oval, bacilliform basidiospores (Figure 2).

When the mating types of *C. neoformans* strains recovered from either the environment or patient samples have been determined, there has always been a large excess of the 'alpha' mating type over 'a' mating type strains

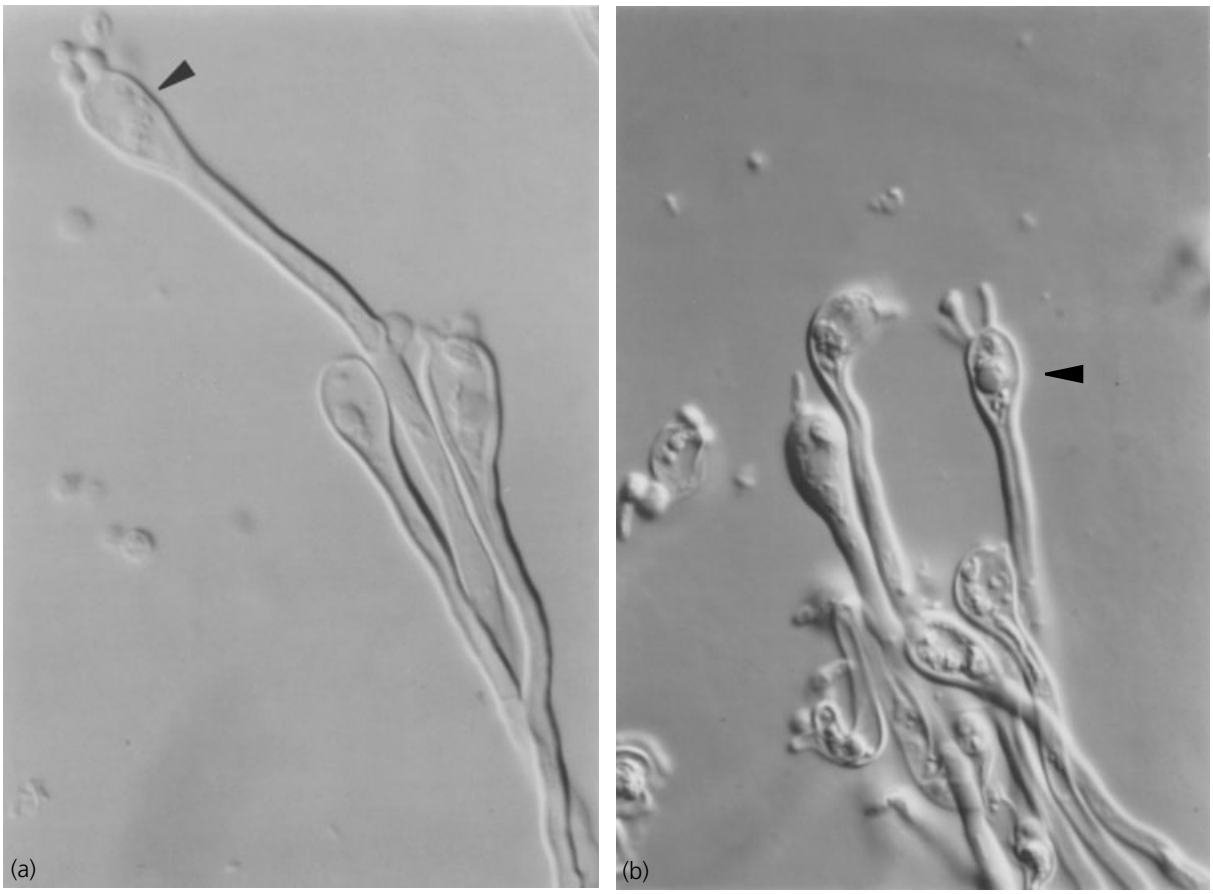

Figure 2 *The teleomorph stages of* **(a)** C. neoformans *var.* neoformans *and* **(b)** C. neoformans *var* gattii. *This stage results from mating between two isolates of the opposite mating type, and is characterized by hyphae containing nuclei from each parent (dikaryotic hyphae). At the end of some hyphae, specialized structures called basidia (arrow) can form. Meiosis occurs in the basidia, and the resulting haploid basidiospores bud off at the apex. Note the shape of the basidiospores of each variety. The basidiospores of var.* neoformans *are round, whereas those of var.* gattii *are elliptical.* **(a)** *Courtesy of Wiley Schell;* **(b)** *courtesy of Michael McGinnis*

(i.e. >95 percent) (Kwon-Chung and Bennett 1978). There has been some evidence for recombination in nature among strains, but the reason for this biased difference in mating type remains unclear. One possibility for predominance of the 'alpha' mating type comes from Wickes et al. (1996), in which they found that several haploid 'alpha' mating type strains were able to form hyphal structures on starvation media. The haploid fruiting formed by these strains produced basidia and basidiospores that were indistinguishable from those produced by hyphae resulting from matings. This ability to form basidiospores by haploid fruiting was independent of serotype, and was only seen in alpha mating type strains. However, in a recent investigation MAT 'a' strains have been observed to produce haploid fruiting (Tscharke et al. 2003), but MAT 'alpha' strains seem to more commonly perform this morphological change.

Growth and Identification

C. neoformans can be grown on a variety of agars, and develops into white, mucoid colonies that usually become visible to the naked eye within 48 hours of incubation. The mucoid appearance of the colonies is caused by the yeast cell's production of a well-defined polysaccharide capsule. The optimal growth temperature of most cryptococcol strains ranges between 30 and 35°C, and the maximally tolerated temperature is approximately 40°C. *C. neoformans* var. *grubii* generally is more thermotolerant than the other two varieties (Martinez et al. 2001). On rich media at 30°C the doubling time for most cryptococcal strains is between 2.5 and 6 hours. The yeast forms are round to oval with diameters between 2.5 and 10 μm and hyphae are never seen with the yeast forms in nutrient media, although pseudohyphal and hyphal forms can sometimes be found when the yeast cells are stressed by either harsh environmental conditions such as elevated temperatures or under nutrient-poor conditions.

In the clinical microbiology laboratory, *C. neoformans* can be readily differentiated from other yeasts on the basis of morphology and biochemical tests. The finding of a mucoid colony on an agar plate is usually the first clue to the presence of *C. neoformans* from a clinical

specimen. This suspicion is further heightened by observing encapsulated, budding yeasts on an India ink preparation of the colony (see Figure 1). The rapid urease test is another presumptive means for identifying the yeasts as *C. neoformans*. Virtually all cryptococci (both *neoformans* and non-*neoformans* species) have the enzyme urease and thus can hydrolyze urea to ammonia, and increase the ambient pH. This property can be detected by using various broths containing urea and a pH marker. As cryptococci have large amounts of urease, positive results using such tests can be seen within 15 minutes (Zimmer and Roberts 1979). The identification of *C. neoformans* specifically can be confirmed by using various biochemical tests, and most clinical laboratories use a battery of biochemical tests contained in commercially available kits. Among the cryptococci, *C. neoformans* is the only one that possesses prominent laccase activity, and testing for its presence is another means of accurate identification. This feature can be detected by culturing the isolated yeasts on special agars such as niger seed agar, birdseed agar, caffeic acid, or dopamine agar, and examining for the growth of brown or black colonies (melanin-positive). These assays are particularly helpful when attempting to identify cryptococci from environmental sources with contamination by other fungi and bacteria. However, most clinical microbiology laboratories do not use these special agars because of the expense of keeping them, and instead depend on the biochemical testing. The yeast forms of cryptococci can be identified in histopathological specimens by using mucicarmine or alcian blue staining of histopathological specimens to demonstrate that the yeast forms possess a polysaccharide capsule (Figure 3). There may be strains with a variety of capsule sizes in tissue but only rarely is a true hypocapsular strain detected in tissue. Finally, a Fontana–Masson stain, although not specific for melanin, can demonstrate production of melanin by these yeasts in tissue.

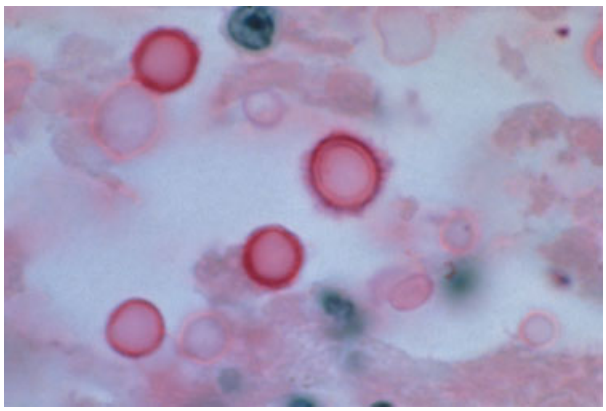

Figure 3 *Histopathology slide of the lung of a patient with cryptococcal pneumonia. The yeasts are easily identified in tissue and the bright red staining around the yeast body demonstrates how this mucicarmine stain identifies the polysaccharide capsule of* C. neoformans.

Capsule

The polysaccharide capsule that surrounds *C. neoformans* is easily observed when yeast cells from the site of infection are examined under the microscope in a suspension of India ink (the ink particles serve to outline the capsule, and make it appear as a clear area or halo surrounding the yeasts) (see Figure 1). Capsule thickness can vary, and in some isolates the capsule can account for more than 50 percent of the diameter of the yeast cells. The capsule is an important virulence determinant for *C. neoformans*, and it is considered to be one of the 3 'classic' virulence factors of cryptococci (the other two are melanin production and growth at 37°C which are discussed in the sections on Melanin production and Growth at 37°C below). Mutant cryptococci that are either hypocapsular or acapsular are consistently less virulent in animal models than encapsulated strains (Chang and Kwon-Chung 1994), and are more easily taken up by white blood cells in in vitro assays (Bulmer et al. 1967; Kozel and Cazin 1971; Fromtling et al. 1982; Kozel and Gotschlich 1982). Infections caused by capsule-free or poorly encapsulated strains are associated with less severe disease (Farmer and Komorowski 1973; Levinson et al. 1974; Milchgrub et al. 1990). The major polysaccharide present in the capsule is glucuronoxylomannan. It is the variable structure of this polysaccharide that accounts for the different serotypes. The glucuronoxylomannans of the serotypes differ in the degree of mannosyl substitution and in the molar ratios of mannose, xylose, and glucuronic acid (Turner and Cherniak 1991). This capsule material can be released from the yeast and extrudes into various tissues such as blood and CSF. It is this antigen that is detected by the cryptococcal antigen test which is so effective for diagnosis in the clinics (see section on Meningoencephalitis below).

Several physiological conditions have been linked to the growth and regulation of the capsule in *C. neoformans*. The P_{CO_2} concentration of the surrounding environment, ferric iron availability, and presence of serum can dramatically influence capsular size (Granger et al. 1985; Vartivarian et al. 1993; Zargoza et al. 2003). Cryptococcal polysaccharide synthesis and capsule size are increased additively by physiological concentrations of CO_2, limitation of ferric iron, and addition of serum. Most *C. neoformans* strains appear to produce large capsules at physiological P_{CO_2} concentrations and small capsules when exposed to environmental P_{CO_2} concentrations. This environmental regulation of the capsule appears to be congruent with the yeast's needs as a pathogen. For example, a small capsule is required for deposition in the host's airways from their environmental source, but a large capsule is needed for protection against the host's defenses. As *C. neoformans* does not produce hydroxamate siderophores for iron acquisi-

tion (Jacobson and Petro 1987), but responds to iron in the environment, it is likely that there are specific iron receptors on the surface of *C. neoformans*; iron is extremely important to the growth of *C. neoformans* (Jacobson and Vartivarian 1992). Several genes that are essential for capsule production and regulation have recently been identified (Chang and Kwon-Chung 1994, 1999; Moyrand et al. 2002). It is also clear that there are signaling pathways such as the cAMP pathway that control the expression of capsule production (Alspaugh et al. 1997) and the capsule appears to attach to the cell wall through glucan linkages (Reese and Doering 2003). Understanding the formation of this unique structure is underway, but further insights will require continued focus on molecular and biochemical aspects of the formation and maintenance of this imposing physical structure.

The impact of the capsular polysaccharide on host immunity can be profound. For instance, it has been shown to have the following effects on immunity:

- antiphagocytosis
- depletes complement
- decreases antibody responsiveness
- inhibits leukocyte migration
- dysregulates cytokine secretion
- produces brain edema
- enhances human immunodificiency virus (HIV) infection
- interferes with antigen presentation
- produces selectin and tumor necrosis factor receptor loss
- creates highly negative charge around cells
- extrudes itself into the intracellular environment with potential local toxicity for cellular organelles (Casadevall and Perfect 1998).

Since a major component of the yeasts' growth in the host is intracellular (Feldmesser et al. 2001), the negative impact of the polysaccharide extruded into the interior of a phagocytic host cell is likely to be profound. The capsule is a major virulence factor through its multipotential ability to abrogate a successful host immune challenge.

Melanin production

The presence of a functional laccase(s) enzyme in *C. neoformans* is unique among other members of this genus. This enzyme participates in the conversion of diphenolic compounds into melanin. The production of this pigment by a simple biochemical pathway is both a means for identifying *C. neoformans* in the laboratory and also a major virulence factor. It is thought that this enzyme is bound on the inner aspect of the cytoplasmic membrane, and the primary gene encoding for this enzyme has been identified and characterized (Polacheck et al. 1982). A wide variety of diphenolic substrates can be utilized by the cryptococcal laccase, including catecholamines such as dopamine and norepinephrine. The ability to produce melanin by a variety of pathogenic fungi has been touted as a potential protectant from host cell damage. Cryptococcal mutants lacking laccase activity have been found to be attenuated in animal models of infection (Salas et al. 1996) and are also killed by the epinephrine oxidative system in the presence of a transition metal ion and hydrogen peroxide compared to the more resistant laccase-positive cells (Kwon-Chung et al. 1982; Rhodes et al. 1982; Polacheck et al. 1990). The melanin produced by degradation of these catecholamines accumulates in the cell wall and may provide protection against a variety of host oxidative stresses (Jacobson and Emery 1991). Importantly, the ability to form melanin in the host has been demonstrated (Nosanchuk et al. 2000a; Rosas et al. 2000). The ability to degrade naturally occurring catecholamines such as norepinephrine to an antioxidant to protect the yeast when it is in the catecholamine-rich CNS may partially explain its propensity to infect the central nervous system. Besides melanin's antioxidant properties, it may also provide other protections for the yeast including:

- cell wall support or integrity
- alterations in cell wall charge
- interference with T-cell response
- abrogation of antibody-mediated phagocytosis
- protection from temperature changes and antifungal agents (Casadevall and Perfect 1998).

Growth at 37°C

A very basic trait for all pathogenic fungi is their ability to grow well at 37°C. In fact, mutants of *C. neoformans* that cannot grow well at 37°C are avirulent even when they possess capsules and laccase activity (Kwon-Chung et al. 1982). Cryptococcal strains differ in their rates of growth at 37°C and their virulence is directly related to their rate of growth at physiological temperatures. Very high mammalian body temperatures of 39–40°C will significantly slow the growth rate of most *C. neoformans* strains and at this temperature the yeasts will actually begin to produce intracellular vacuolization with aberrant budding patterns and pseudohyphal structures. The varieties *gattii* and *neoformans* appear to be more sensitive to high temperatures than var. *grubii*, and at 40°C most strains of var. *gattii* and var. *neoformans* will lose viability within 24 hours (Martinez et al. 2001). Furthermore, it is clear that high-temperature growth is under genetic control with the isolation of a series of temperature-sensitive mutants. Recent work, beginning with the findings of Odom et al., showing that calcineurin in *C. neoformans* was important to high-temperature growth (Odom et al. 1997), has begun to unravel the molecular networks and specific genes necessary for *C. neoformans*

to grow well at mammalian body temperatures (Alspaugh et al. 2000; Erickson et al. 2001). This includes both the signaling pathways of calcineurin and *RAS* and includes biochemical pathways such as the stress protectant sugar trehalose and certain vacuolar functions (Erickson et al. 2001).

ECOLOGY

C. neoformans was first identified in nature by Sanfelice in 1894 from samples of peach juice (Sanfelice 1894). Although fruits are currently not thought to be a significant environmental source for this fungus, certain species of trees are a potential reservoir or habitat for it. *C. neoformans* var. *grubii* can also be found in soil contaminated by bird guano. Its ability to survive within scavenging predators of the soil has led to studies of *C. neoformans* growth in ameba (Steenbergen et al. 2001), dictosteylium (Steenbergen et al. 2003), and nematodes such as *Caenorhabditis elegans* (Mylonakis et al. 2002).

C. neoformans var. *neoformans* and var. *grubii*

Emmons isolated *C. neoformans* from soil, pigeon droppings, and pigeon nests in the 1950s (Emmons 1951, 1955). Since those initial reports, this fungus has been found in soil samples from around the world. The soils that most commonly yield *C. neoformans* var. *neoformans* and var. *grubii* have been frequented by birds, especially pigeons and chickens. For instance, this fungus has commonly been isolated from roosting sites of pigeons in which their droppings had accumulated over many years. Guano from other birds such as canaries, parrots, and turkeys has also yielded *C. neoformans* var. *neoformans* and var. *grubii*. It is not known why there is a frequent association of pigeons with *C. neoformans* because pigeons rarely develop disease with *C. neoformans* in nature. This probably results from the fact that the normal body temperature for a pigeon is above 40°C and most cryptococci are inhibited by these elevated temperatures (Littman and Borok 1968). Pigeons can, however, harbor the yeast as saprophytes in their gastrointestinal tracts. In fact, when force-fed *C. neoformans*, pigeons had viable yeasts cultured from their crops for more than 2 months (Swinne-Desgain 1976). Thus birds could act as a vector for spread of the fungus in the environment.

This fungus can metabolize low-molecular-weight nitrogenous compounds, such as creatinine, which are present in bird guano, and it has been postulated that there is a natural selection for *C. neoformans* to inhabit and grow in this niche. The exact role of pigeon guano in the pathogenesis of human infections is obscure. Only rarely can one elicit a history of intense pigeon exposure from patients with cryptococcosis (Fessel 1993), and there have never been outbreaks of the disease traced back to pigeon-roosting areas. However, there is a case report of infection in an immunosuppressed patient linked to a strain found in a pet bird's cage (Nosanchuk et al. 2000b).

C. neoformans var. *neoformans* and var. *grubii* have occasionally been isolated from rotting vegetation and wood of trees (Pal and Mehrotra 1985). A report from Brazil demonstrated that var. *grubii* isolates could be cultured from areas of wood decay existing on living trees (Lazera et al. 1996). It is probable that decaying wood of certain trees is one natural ecological niche for *C. neoformans* var. *neoformans* and var. *grubii*.

C. neoformans var. *gattii*

As opposed to var. *neoformans* and var. *grubii*, var. *gattii* has never been cultured from bird guano. There have, however, been several environmental niches identified for var. *gattii* strains. Ellis and Pfeiffer were able to culture *C. neoformans* var. *gattii* from vegetation associated with river red gum trees (*Eucalyptus camaldulensis*) and forest red gum trees (*Eucalyptus tereticornis*) in Australia (Ellis and Pfeiffer 1990; Pfeiffer and Ellis 1992). These trees were exported from Australia to various parts of the world, and it was reasoned that var. *gattii* may have been exported along with the trees. These investigators were able to culture a strain of var. *gattii* from a river red gum tree in San Francisco, CA (Pfeiffer and Ellis 1991). There may also be an association with var. *gattii* release of spores with the flowering of the trees since cultures of air samples taken from under flowering trees can yield cryptococci, whereas samples taken when the trees are not in flower do not. Areas of the world that have river red gum trees in the environment also have a fair number of var. *gattii* cryptococcal strains involved in their cases of cryptococcosis. However, a recent significant outbreak of cryptococcosis on Vancouver Island in British Columbia demonstrated that other trees such as fir and oak will also contain var. *gattii* strains (Stephen et al. 2002) and possibly become a vector for human disease.

EPIDEMIOLOGY

Cryptococcosis is a worldwide infection which only rarely causes disseminated disease in healthy individuals. Most patients with cryptococcosis have evidence of some underlying immunocompromising condition. The most common of these underlying conditions worldwide is AIDS, followed by prolonged treatment with corticosteroids, organ transplantation, malignancies, and sarcoidosis (Pappas et al. 2001; Perfect and Casadevall 2002). However, recent estimates are that if patients with HIV infection are excluded, approximately 20 percent of patients with cryptococcosis will present with no apparent underlying disease or risk factor (Pappas et al. 2001).

Cryptococcosis is not a routinely reportable disease in the USA, so accurate nationwide estimates of prevalence are difficult to determine. However, in 1992, before the availability of highly active antiretroviral therapy (HAART), an incidence of 4.9 cases of cryptococcosis per 100 000 population was reported in both San Francisco, CA and Atlanta, GA (Pinner et al. 1993). Between 1992 and 1994 in four large metropolitan areas within the USA, the incidence of infection ranged between 0.2 to 0.9 cases/100 000 population. With widespread use of fluconazole and the introduction of HAART, this lower rate of infection has continued in the US cities. Cryptococcosis in AIDS within developed countries has generally focused on a group of patients with less access to medical care (Mirza et al. 2002). Prior to HAART it was estimated that 6–10 percent of all patients with AIDS in the USA, western Europe, and Australia were diagnosed with cryptococcosis, making it the fourth most common opportunistic infection in this population (Kovacs et al. 1985; Powderly 1993). The rate of cryptococcal meningitis in patients with AIDS is even higher in sub-Saharan Africa where rates of 15–30 percent have been encountered (Clumeck et al. 1984; Van de Perre et al. 1984; Powderly 1993), and HAART has yet to make an impact on the incidence of cryptococcal disease in many of these countries. It can be anticipated that the numbers of cases of cryptococcal meningitis in the world will continue to mirror the worldwide control of the HIV epidemic. In addition, in developed countries more individuals are undergoing organ transplantation and aggressive cancer chemotherapeutic regimens and thus the pool of at-risk patients continues to enlarge.

Interestingly, there are only rare reports of outbreaks of cryptococcosis traced to a common source such as the recent Vancouver Island outbreak (Stephen et al. 2002), and this is unlike the occasional known outbreaks of infection from an environmental source with the classic dimorphic fungi. There have been no documented cases of spread of infection from person to person through routine contact, but there are several cases of cryptococcosis produced by transplantation of infected tissue (Beyt and Waltman 1978; Kanj et al. 1996). *C. neoformans* occasionally has been introduced into a host through direct trauma with a fomite (Glaser and Garden 1985; Casadevall et al. 1994), although inhalation into the lung is the most common route of initial infection. Cryptococcosis appears to be primarily a disease of adults because it is uncommon to produce disease in children, even in those with AIDS. The reason for the reduced incidence of disease in children is unclear and it occurs despite the fact that studies have shown that children are exposed to this fungus at a young age (Chen et al. 1999; Goldman et al. 2001).

The frequency of serotypes or varieties of *C. neoformans* strains that have been found in cases of cryptococcosis varies according to geographical location and whether the patient has HIV infection as a predisposing condition. Kwon-Chung and Bennett did an extensive review of 725 clinical isolates of *C. neoformans* obtained from around the world before the AIDS epidemic (Kwon-Chung and Bennett 1984). These investigators found that, overall, var. *neoformans* and *grubii* were far more common than var. *gattii*, and accounted for more than 80 percent of all isolates, and of these isolates 80 percent were var. *grubii*. The var. *gattii* isolates were almost exclusively found in tropical and subtropical areas such as southern California, Hawaii, Brazil, Australia, Southeast Asia, and Central Africa. This geographical restriction is most probably the result of the ecological relationship of var. *gattii* with certain trees such as eucalyptus and firs. Serotype D strains (var. *neoformans*) predominately come from Europe, especially Denmark, Germany, Italy, and Switzerland. Isolates from the UK consisted of 87 percent serotype A and 13 percent serotypes B and C, whereas isolates from continental USA, excluding southern California, were 81 percent serotype A, 7 percent serotype D, and 6 percent serotypes B and C (some had no identifiable serotype)(-Bennett et al. 1977; Friedman 1983; Kwon-Chung and Bennett 1984). Before the AIDS epidemic, the serotypes of cryptococcal strains isolated from patients living in southern California had a higher proportion of serotypes B and C when compared with the rest of the USA. It is important to keep in mind that these isolates were all obtained before the AIDS epidemic. The vast majority of cryptococcal isolates from patients with AIDS have been var. *neoformans* or var. *grubii*, regardless of geographical location. This is most strikingly demonstrated by data from Central Africa. Over 90 percent of isolates obtained before 1970 from Central Africa were var. *gattii*. However, among the many cryptococcal strains obtained from patients with AIDS in Central Africa, there has been only one var. *gattii* strain identified (Kapend'a et al. 1987). The reason(s) why patients with AIDS are more likely to be infected by var. *neoformans* or var. *grubii* strains is not known. It is hypothesized that differences in infection patterns are the result of certain epidemiologic factors of exposure. For instance, HIV remains a predominantly urban infection; patients with AIDS may not be exposed to the rural environmental niches of var. *gattii* strains. However, it may also be possible that var. *neoformans* or var. *grubii* strains more commonly produce dormant infections that are reactivated when immunity is impaired during HIV infection compared with var. *gattii* in which disease may occur primarily during initial infection.

PATHOPHYSIOLOGY AND IMMUNOLOGY

The exact pathophysiology of cryptococcosis is not known for certain, but a reasonable scheme starts with the host coming into contact with cryptococci from the environment through inhalation of small yeasts or basi-

diospores, with their subsequent deposition in the pulmonary alveoli. It is advantageous for the infecting propagules to be as small as possible because this would favor deposition into the lung, and it is for this reason that some investigators have postulated that the infectious propagules of *C. neoformans* are the basidiospores produced during the sexual cycle or with haploid fruiting. Basidiospores are smaller than the yeast cells obtained in clinical specimens and appear to be the ideal size for inhalation. With identification of the haploid fruiting process, spores can be made in the environment without the need for mating. However, there have been small poorly encapsulated yeasts of sizes consistent with basidiospores isolated from the environment (Neilson et al. 1977; Ruiz and Bulmer 1980), and it must be stressed that the basidiospore structures have yet to be directly observed in nature.

Once the yeasts or spores arrive at the alveoli, the earliest innate immune response elicited is composed of alveolar macrophages, which is then followed by the arrival of polymorphonuclear cells, activated macrophages, and lymphocytes. Data from both experimental animal and human experiments show that the protective components of the immune system for cryptococcosis are primarily cell-mediated, and are composed of activated alveolar macrophages, natural killer (NK) cells and both CD4+ and CD8+ lymphocytes. Several studies have indicated that CD4+ and CD8+ cells are especially important in containing the spread of cryptococci from the site of initial infection in the lung to the central nervous system (Hill and Harmsen 1991; Mody et al. 1993, 1994).

Patients with intact immune systems can mount an effective, coordinated response to cryptococcal infections, and the result is a granulomatous-type inflammatory lesion which is primarily driven by the Th1 cytokine responses. A series of studies have identified the positive features of IL-2, IL-12, and interferon-gamma for an effective immune response against *C. neoformans*. A Th2 response is associated with an ineffective inflammatory reaction. Most primary infections of the lungs are asymptomatic in immunocompetent individuals because they are readily contained by the immune system. As cryptococci are widespread in nature and yet cryptococcosis is a rare event, it is assumed that subclinical primary infections are common in the general population. Unfortunately, there is not a standardized skin test to prove this hypothesis. Besides the host's immune status, there may be some contribution of inoculum size or particular virulence of infecting strain as to whether or not immunocompetent individuals become symptomatic during primary infection.

Elegant postmortem studies have shown the existence of pulmonary foci and hilar lymph nodes containing yeasts during autopsies in individuals who had no antecedent respiratory complaints (Baker and Haugen 1955; Baker 1976). These focal areas of quiescent infection have the potential to disseminate should the host's immune system become impaired. The widespread and acute presentation of cryptococcosis in patients with AIDS shows that the lack of an effective cell-mediated immune response with deterioration in numbers and functions of CD4+ cells results in a rapid dissemination of yeasts throughout the body with a higher fungal burden in tissues compared to apparently immunocompetent individuals. Disseminated cryptococcosis in the immunocompromised population may represent either reactivation of latent infection or in some cases a primary infection with immediate disease due to an initial ineffective immune response.

Although the cell-mediated arm of the immune system is the primary host reaction in responding to invading cryptococci, antibodies directed against *C. neoformans* can be protective. For instance, passive immunization of mice with monoclonal antibodies directed against the capsule can protect and modulate infection (Mukherjee et al. 1992, 1993, 1994). The basis for the humoral protection may be the result of opsonization or decreased levels of glucuronoxylomannan in tissue. As a result of the protection afforded by antibodies in animal models of infection, there remains hope of developing a vaccine for use in people at high risk for cryptococcosis or the use of serotherapy in the treatment of active disease. Both polyclonal and monoclonal anticryptococcal antibodies have been infused and evaluated in patients, but further studies are needed to define their clinical effectiveness.

C. neoformans appears to have some type of neurotropism in humans because of its common propensity to cause meningoencephalitis. The reasons for this unique presentation are not known. There is some speculation that because of its ability to use catecholamines as substrates for melaninogenesis, *C. neoformans* has a survival advantage in the CNS where these products occur in large amounts. It is also possible that this yeast has special surface properties or has the ability to reside within host cells and traverse across the blood–brain barrier within them. Once the yeast is in the CNS compartment, the relatively immunologically sequestered environment of the CNS allows it to grow easily.

CLINICAL PRESENTATION

Meningoencephalitis

Cryptococcal meningoencephalitis is the most frequently encountered manifestation of cryptococcosis. The term 'meningoencephalitis' is more appropriate than meningitis because pathological inspection of human cases shows that the underlying brain parenchyma is generally involved, although radiographically it may not be

apparent. The clinical presentation of this infection in AIDS versus non-AIDS patients is slightly different (Table 2). This clinical difference results from the more severe immunosuppression generally observed in patients with AIDS. It is a manifestation of a higher burden of yeasts and a reduced host inflammatory response. When cryptococcal meningoencephalitis is diagnosed in the setting of HIV infection, it is almost always in patients with CD4 lymphocyte counts lower than 100 cells/mm^3. The features of CNS cryptococcosis in patients with AIDS collected from several different series are shown in Table 3 (Kovacs et al. 1985; Eng et al. 1986; Zuger et al. 1986; Chuck and Sande 1989; Clark et al. 1990a; Saag et al. 1992). This infection was the AIDS-defining illness for 60 percent of the patients in these series. The onset of symptoms was usually over a period of 1–2 weeks, and the three most common symptoms were headache, fever, and malaise, seen in 83, 75, and 68 percent of patients, respectively. Symptoms such as stiff neck, photophobia, and vomiting were seen only in a minority of patients. The initial physical examination revealed altered mentation in 24 percent of the patients and focal neurological deficits in 6 percent (Table 3). Rarely, patients with cryptococcal meningitis and severe immunosuppression can present in a fulminant fashion with rapidly developing coma and death.

By contrast, patients without AIDS usually have symptoms for a longer period of time. Those less common patients with no obvious underlying risk factors can have symptoms lasting for months before a diagnosis is made. However, most patients present with signs and symptoms of subacute meningoencephalitis. Headaches, fever, lethargy, coma, personality changes, and memory loss can develop over weeks. However, there can be tremendous variability in the clinical presentation. Some patients may present with severe headaches for only a few days, intermittent headaches for months, or no headaches at all. The presence of a headache may, in fact, be an important positive prognostic factor by allowing an earlier diagnosis (Dismukes et al. 1987).

It is generally thought that there is no difference in the clinical presentation of patients with cryptococcal meningoencephalitis based on the serotype of the infecting strain. However, the possibility of strain influence should not be entirely neglected. Reviews of cryptococcosis in Australia compared the clinical features of patients with infections caused by the varieties (Speed and Dunt 1995). In contrast to the patients with infection resulting from var. *neoformans* or var. *grubii* strains, the patients with var. *gattii* were more likely to have neurological complications at presentation such as hydrocephalus and cranial nerve deficits. These differences might be explained by the possibility that var. *gattii* strains are generally less virulent than var. *neoformans* or var. *grubii*. Thus, less virulent cryptococcal strains might allow a more robust immune response by the host. The active inflammatory response may account for the insidious presentation and focal neurological signs. It is again interesting to note that in several large reviews of *C. neoformans* there were few infections caused by var. *gattii* strains in highly immunosuppressed patients.

Lung

Despite the probability that most pulmonary infections with cryptococci are asymptomatic, hundreds of cases of symptomatic pulmonary cryptococcosis in apparently immunocompetent hosts have been described in the medical literature (Kent and Layton 1962; Newberry et al. 1967; Tynes et al. 1968; Warr et al. 1968; Hammerman et al. 1973; Rosenheim and Schwarz 1975; Paillas et al. 1982; Henson and Hill 1984; Cohen 1985; McDonnell and Hutchins 1985; Diamond and Levitz 1988). Campbell's comprehensive review of the English medical literature up to 1965 remains the most complete description of primary pulmonary cryptococcosis (Campbell 1966). This review suggests that primary pulmonary cryptococcosis in the immunocompetent host may present asymptomatically in 32 percent, i.e. abnormal findings on a chest x-ray taken for other reasons. However, most patients described in this review presented with symptoms including cough (54 percent), chest pain (46 percent), sputum production (32 percent), weight loss and fever (26 percent each), and hemoptysis (18 percent). Other presentations including dyspnea, night sweats, and superior vena cava obstruction are rarer (Menon and Rajamani 1976; Lehmann et al. 1984). Patients may simply present with airway colonization (Duperval et al. 1977), but this colonized state is frequently observed in patients with underlying chronic lung disease.

Table 2 *Comparison of cryptococcal meningoencephalitis in AIDS versus non-AIDS patients*

Findings	Patients with AIDS	Patients without AIDS
Duration of symptoms	Usually <2 weeks	Usually <2 weeks
Positive India ink of CSF	Approx. 75%	Approx 50%
CSF antigen titer (1:1,024	Common	Rare
Serum antigen positive	Common	Common
CSF white blood cells (20/μl	Very common	Rare
Extraneural involvement	Common	Rare
Opening pressure (200 mm	Common	Less common

Table 3 *Clinical features of cryptococcal meningoencephalitis in patients with AIDS*

Clinical feature	Frequency among patients with AIDS (%)
Headache	83
Fever	75
Malaise	68
Vomiting	42
Meningismus	32
Altered mentation	24
Photophobia	19
Focal neurological deficit	6

Immunocompromised patients with cryptococcal pneumonia may have a more rapid symptomatic clinical course than that seen in immunocompetent hosts. Although *C. neoformans* typically enters through the lungs, in the immunocompromised host it tends to disseminate rapidly or reactivate from a primary focus, eventually to establish infection within the CNS; hence these patients may present with a meningitis syndrome rather than a pulmonary syndrome. However, overwhelming cryptococcal pneumonia with adult respiratory distress syndrome can also occur on initial presentation (Kent and Layton 1962; Henson and Hill 1984; Murray et al. 1988). These immunocompromised patients include those with HIV infection, cirrhosis, diabetes, Cushing's syndrome, sarcoidosis, chronic leukemia, lymphoma, those undergoing treatment with glucocorticoids, and solid organ transplant recipients (Kerkering et al., 1981; Blanc et al. 1982; Kramer et al. 1983; Christoph 1990; Cameron et al. 1991). Kerkering et al., in a classic retrospective review of pulmonary cryptococcosis, described 41 patients with pulmonary infection, 34 of whom had an underlying immunocompromising condition other than HIV (Kerkering et al., 1981). Twenty-nine of these patients developed disseminated disease, but only one of the patients with disseminated disease was identified as immunocompetent. Unlike immunocompetent hosts who may have an inapparent pneumonitis, 83 percent of the immunosuppressed patients had constitutional symptoms. The most common presenting symptoms were:

- fever 63 percent
- malaise 61 percent
- chest pain 44 percent
- weight loss 37 percent
- dyspnea 27 percent
- night sweats 24 percent
- cough 17 percent
- hemoptysis and headache 7 percent each.

Subsequent to the diagnosis of pulmonary cryptococcosis, dissemination to the meninges occurred in 25 patients within 2–20 weeks of the pulmonary presentation. All the patients had abnormal chest x-rays. The most common findings were alveolar or interstitial infiltrates, followed by single or multiple coin lesions, masses, cavitary lesions, and pleural effusions. In this review the outcome of infection clearly supported the recommendation that immunodeficient hosts with pulmonary cryptococcosis require antifungal therapy (Kerkering et al. 1981).

Pulmonary cryptococcosis is less common than meningitis as a presenting complaint in patients with AIDS, but is well described. Pulmonary cryptococcosis in patients with HIV infection has slightly different manifestations than in other types of immunocompromised hosts (Wasser and Talavera 1987; Khardori et al. 1988; Chechani and Kamholz 1990; Clark et al. 1990b; Cameron et al. 1991). In one series of pulmonary manifestations of AIDS, *C. neoformans* was the implicated pathogen in approximately 10 percent of the cases (Suster et al. 1986). Almost all patients with AIDS present with symptoms, including:

- fever 81 percent
- cough 63 percent
- dyspnea 50 percent
- weight loss 47 percent
- headache 41 percent
- occasionally pleuritic chest pain and hemoptysis.

Dissemination of cryptococci, particularly to the meninges or blood, occurred in 94 percent of the patients with pulmonary disease, based on the results from two studies (Wasser and Talavera 1987; Cameron et al. 1991). Physical examination findings were not stated in most reports, but may include lymphadenopathy, rales, tachypnea, and splenomegaly (Cameron et al. 1991). Concomitant second infections with other opportunistic pathogens, including *Pneumocystis jiroveci*, *Mycobacteriurn avium-intracellulare*, cytomegalovirus, and *Histoplasma capsulatum* var. *capsulatum*, can occur in conjunction with pulmonary cryptococcosis (Chechani and Kamholz 1990; Clark et al. 1990b; Cameron et al. 1991). In addition, *C. neoformans* pneumonia may occur as a consequence of adjunctive steroid therapy for *P. jiroveci* (Lambertus et al. 1990) and its clinical presentation can be confused in AIDS patients with pneumocystis pneumonia.

Skin

It has been known for over 50 years that *C. neoformans* infection can produce a variety of skin lesions. Littman and Zimmerman (1956), in their classic monograph, described the observations of Cawley, Grekin, and Curtis (Cawley et al. 1950) on cutaneous cryptococcosis. It was noted that skin lesions could appear as acneiform lesions, purpura, papules, vesicles, nodules, tumors, abscesses, ulcers, superficial granulomas, plaques resembling ecchymoses, and sinus tracts. Recent case reports in AIDS patients have shown an

even more expanded variety of skin presentations to include herpetiformis- (Borton and Wintroub 1984) or molluscum contagiosum-like lesions (Concus et al. 1988). Furthermore, cellulitis (Gauder 1977; Mayers et al. 1981) around an intravenous catheter, which may appear similar to a bacterial infection, can be caused by *C. neoformans* in patients at high risk for infection (Sarosi et al. 1971; Schupbach et al. 1976). The impressive array of cutaneous presentations of infection emphasizes the particular need for skin biopsy and proper histopathology of all new skin lesions for diagnosis in immunocompromised patients. These sentinel lesions may be the first presentation of disseminated cryptococcosis, and the identification of cutaneous cryptococcosis represents disseminated disease in most cases. However, direct inoculation of *C. neoformans* into the skin with production of primary infection has been described (Neuville et al. 2003) and it has been linked to both direct trauma with contaminated fomites and/or laboratory or clinical accidents (Glaser and Garden 1985; Casadevall et al. 1994). There are some cryptococcal strains which appear to have a tropism for skin in animal models and *C. neoformans* var. *neoformans* appears to infect the skin more commonly than the other varieties. Finally, in solid organ transplant recipients with the use of immunosuppressives like tacrolimus, some institutions have begun to observe more infections with *Cryptococcus* limited to the skin (Singh et al. 1997).

Prostate

The prostate gland is known to be a site for cryptococcal infection (Braman 1981). Infection at this site typically does not cause symptoms of prostatitis, but these yeasts have been isolated from prostate tissue and blood after urological procedures (Plunkett et al. 1981). *C. neoformans* has been described to cause a penile ulcer (Perfect and Seaworth 1985) and a vulvar lesion (Blocker et al. 1987), but there have been no reports of conjugal spread of this infection. The significance of genitourinary infection for clinical disease may reside in the prostate's potential as a protected sanctuary for this yeast during drug treatment. In careful follow-up of patients with AIDS-associated cryptococcosis, it has frequently been found that routine urine or seminal fluid cultures for cryptococci after prostatic massage were positive at the end of an extended course of therapy (Larsen et al. 1989; Staib et al. 1989). However, it is not certain that the prostatic foci of infection are the reasons why some patients with cryptococcosis relapse after therapy is stopped.

Eye

In patients with disseminated cryptococcosis, ocular involvement with *C. neoformans* is not a rare event (Blachie et al. 1985). Before HIV infection, one series found ocular signs and symptoms in approximately 45 percent of patients (Okun and Butler 1964). From ocular palsies to involvement of the retina (Crump et al. 1992), which can also be simultaneously infected with other pathogens such as HIV or cytomegalovirus (Doft and Curtin 1982), ocular cryptococcosis is a sight-threatening infection. In fact, most cases of cryptococcal endophthalmitis lead to severe visual loss with only an occasional case successfully managed (Denning et al. 1991a). In about a quarter of cases, eye involvement may present before the diagnosis of cryptococcal meningoencephalitis (Crump et al. 1992).

There have been recent descriptions of catastrophic visual loss in patients without evidence of cryptococcal endophthalmitis (Johnston et al. 1992; Rex et al. 1993). Funduscopic examination is either normal or demonstrates papilledema. Investigators have suggested that two pathogenic mechanisms exist for this complication. One group has rapid visual loss in a period as short as 12 hours and a clinical syndrome suggestive of optic neuritis with the optic nerve possibly infiltrated with yeasts. Few therapeutic maneuvers have been successful for this form of visual loss. The second group presents with slow visual loss which typically begins later in therapy and slowly progresses over weeks to months. In this group, symptoms may be related to increased intracranial pressure and treatment of these pressure conditions with shunts, medications, or optic nerve fenestrations may halt progression of the visual loss.

The eye may also be the entry site for *C. neoformans* infection. For example, one case of a corneal transplant transmitting this yeast from the donor to recipient was reported with eventual development of meningitis in the patient (Beyt and Waltman 1978); a second case of cryptococcal keratitis after a keratoplasty has been described (Perry and Donnenfeld 1990); and, finally, the observations that meningitis was only identified after eye involvement have been documented in some cases (Granger et al. 1986; Birkmann and Bennett 1988). All these findings suggest the possibility that trauma to the eye with *C. neoformans* contaminated debris could be a portal of entry for *C. neoformans* in some clinical cases of infection.

DIAGNOSIS

Meningoencephalitis

The clinical diagnosis of cryptococcal meningoencephalitis can be very difficult given the subacute onset of symptoms and the nonspecific presentation that many patients can have. The most important point for the diagnosis is to appreciate the signs and symptoms referable to the CNS in high-risk patients, and to consider *C. neoformans* as a possible pathogen in cases of apparently immunocompetent individuals presenting with subacute to chronic meningitis.

A lumbar puncture is necessary for the definitive diagnosis of cryptococcal meningoencephalitis. The opening pressure may be quite elevated, especially in patients with AIDS-associated infections. About two-thirds of patients with AIDS-associated cryptococcal meningoencephalitis described in the literature had initial spinal taps with opening pressures greater than 200 mmH_2O. Examination of the CSF with an India ink preparation will show the typical encapsulated yeast forms in more than 75 percent of patients with AIDS and approximately 50 percent of non-AIDS cases. White blood cell counts of the CSF are characteristically low in AIDS-associated cases (<20 cells/mm^3) and somewhat higher in non-AIDS cases (50–350 cells/mm^3) with a mononuclear cell predominance. Protein and glucose levels in the CSF are usually only slightly abnormal in AIDS-associated cases but cases of cryptococcal meningitis can present with very elevated protein levels and prominent hypoglycorrhachia. On the other hand, the CSF glucose and protein levels, as well as the cell counts, can all be completely normal in some severely immunosuppressed patients with cryptococcal meningoencephalitis.

The diagnosis of meningoencephalitis is firmly established by culture of the yeasts from the CSF. In patients with AIDS-associated infections, CSF cultures are almost always positive because of the high burden of organisms associated with severe immune suppression. In non-AIDS patients, 90 percent will have positive cultures and this rate can be further increased by the culturing of large volumes of CSF (15–20 ml). For those cases where the India ink examination is negative, the cryptococcal polysaccharide antigen assay in the CSF is an important adjunct to diagnosis. Results of the polysaccharide antigen test may be obtained soon after the lumbar puncture is performed and can suggest the presence of the infection before the cultures become positive in the laboratory. The antigen test is both very sensitive and specific (>90 percent). In all patients, the antigen test is positive in more than 90 percent of cases, but false-negative results are slightly more common in non-immunosuppressed patients. On the other hand, false-positive tests can result from infections caused by the fungus *Trichosporon beigelii* or possibly other bacteria (McManus and Jones 1985; Westernik et al. 1987; Chanock et al. 1995). Testing for cryptococcal polysaccharide antigen in serum can also be performed and, in patients with AIDS, the sensitivity of using serum for the antigen test is useful as a screening test in patients who do not initially receive a lumbar puncture in geographical areas with a high incidence of cryptococcal disease. The antigen test can be quantified by testing serial dilutions of CSF or serum. In general, the higher the antigen titer, the higher the burden of yeasts and this finding may help in assessing prognosis. Patients with high polysaccharide antigen titers at the beginning or end of therapy are at higher risk for treatment failure. However, the polysaccharide antigen titers cannot be precisely used to follow therapy and to predict relapse in patients (Powderly et al. 1994) and the use of polysaccharide antigen titers to make treatment decisions can be faulty.

On some occasions, the diagnosis of cryptococcal meningoencephalitis is made only after *C. neoformans* is recovered from another body site. This is especially true in patients with AIDS who have a much higher likelihood of having extraneural disease involving the respiratory tract, urinary tract, or bloodstream at the same time as a CNS infection. There are occasional cases in which a blood culture that was sent during the workup of fever of uncertain etiology in a patient with advanced HIV infection returned positive for *C. neoformans*. Then a subsequent lumbar puncture confirmed the diagnosis of a CNS infection. Blood cultures are positive for cryptococci in about two-thirds of AIDS-associated cases of meningoencephalitis, but occasionally a blood culture is positive without evidence of CNS involvement. However, all patients with a positive serum cryptococcal antigen or blood culture should have a lumbar puncture performed to examine for CNS infection and, in patients that are severely immunosuppressed, these findings should support the diagnosis of disseminated infection and treatment administered for invasive disease.

Radiological imaging of the brain by computed tomography (CT) or magnetic resonance imaging (MRI) is helpful when there is a concern about performing a lumbar puncture in a patient with focal neurological signs or symptoms. It is also useful when it shows significant hydrocephalus because this is an indication for placement of a ventricular shunt. Mass lesions can be seen in about 10 percent of patients with cryptococcal meningoencephalitis. Caution should be exercised in patients with AIDS and mass lesions because lymphomas and cerebral toxoplasmosis can coexist with cryptococcal meningitis. The mass lesions caused by cryptococci may not always be true abscesses or granuloma, but may be gelatinous, cyst-like areas resulting from collection of yeasts and antigen with sparse granulomatous inflammation. It is also important to note that, in following patients with cryptococcomas, these brain lesions may worsen radiographically despite effective therapy and this likely reflects an improved inflammatory reaction during elimination of infection (Hospenthal and Bennett 2000).

Pneumonitis

Diagnosis of infection in immunocompetent hosts has been made antemortem by lung biopsy, for histopathology and/or culture, cytopathology, sputum cultures, and serum antigen testing, in a patient with an abnormal chest x-ray (Smith et al. 1976; Kauffman et al. 1981; Fouret et al. 1985; Davies and Sarosi 1987; Murata et al. 1989). Several publications on cryptococcal pneumonia have reported patients with asymptomatic colonization of the respiratory tree by *C. neoformans* (Tynes et al. 1968; Warr et al. 1968; Hammerman et al. 1973; Subramanian et al. 1982). This condition generally

occurs in patients with an underlying lung disease such as chronic obstructive pulmonary disease. Hence, a sputum culture positive for *C. neoformans* in a patient, with a lack of clinical symptoms or chest x-ray findings of an infiltrative process, needs to be interpreted carefully and may not represent clinical disease. In the normal host, pulmonary *C. neoformans* generally does not disseminate outside the lung, and thus blood, urine, or CSF cultures, and serum or CSF cryptococcal polysaccharide antigens, will be negative. Nevertheless, all patients with cryptococcal pneumonia and/or pulmonary colonization should be evaluated for disseminated disease (Kerkering et al. 1981; Lehmann et al. 1984). Clinicians might consider following patients without symptoms, with no apparent immunocompromising conditions and a negative serum polysaccharide antigen titer, without checking for CNS involvement since their chance of meningitis is very low. All others should be considered for lumbar puncture to rule out meningitis.

Radiographically, *C. neoformans* pneumonia in the normal host may present with well-defined, noncalcified, single or multiple lung nodules, indistinct to mass-like infiltrates, hilar and mediastinal lymphadenopathy, occasionally pleural effusions, and, more rarely, cavitation (Hunt et al. 1976; Young et al. 1980; Zlupko et al. 1980; Paillas et al. 1982; Feigin 1983; McAllister et al. 1984; Murata et al. 1989). Single or multiple peripheral nodules are the most common radiological findings (Figure 4), and many of these infections are discovered when the nodules are aspirated or removed to rule out malignancy (Khoury et al. 1984). These infiltrates may resolve without any specific therapy.

Diagnostic studies in HIV-infected patients with cryptococcal pneumonitis should include arterial P_{O_2}, chest x-ray, cultures, and serum cryptococcal polysaccharide antigen detection. Mild-to-moderate hypoxemia can be found, although both normal P_{O_2} and profound hypoxemia have been documented with cryptococcal pneumonia (Clark et al. 1990b; Cameron et al. 1991). Adult respiratory distress syndrome has also occurred during this infection (Perla et al. 1985; Murray et al. 1988; Similowski et al. 1989). Chest radiographs most often reveal interstitial infiltrates, either focal or diffuse, and lymphadenopathy; unlike immunocompetent and other types of immunocompromised hosts, nodular and alveolar infiltrates are more unusual (Miller and Edelman 1990; Clark et al. 1990b; Cameron et al. 1991). Large masses and pleural effusions are also unusual in AIDS patients (Cameron et al. 1991). As the most common radiological picture is one of interstitial infiltrates, *C. neoformans* pneumonia can easily be confused with *P. jiroveci* pneumonia, a common cause of interstitial infiltrates in patients with AIDS (Loerinc et al. 1988). Cryptococcal serum antigen detection can be extremely helpful while awaiting culture results. As patients with AIDS frequently have disseminated cryptococcosis, positive serum or CSF cryptococcal antigen tests are also frequently detected (Clark et al. 1990b; Cameron et al. 1991).

MANAGEMENT

Meningoencephalitis

For an invasive mycosis, the clinical management of cryptococcosis has been relatively well studied and there is substantial evidence-based data to make therapeutic recommendations. In fact, a group of experts in medical mycology have developed guidelines for the therapy of cryptococcosis (Saag et al. 2000). Despite the studies, there remains a wide range of options and consequences

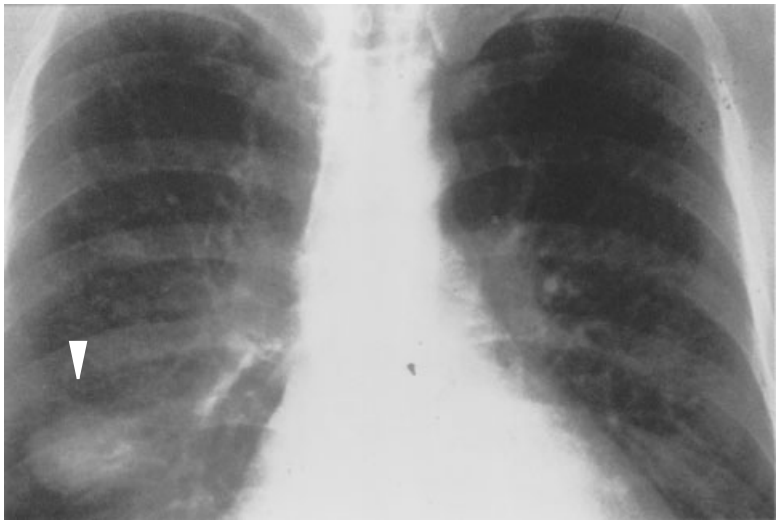

Figure 4 *A chest x-ray from a patient with an asymptomatic nodule in the right lower lung field (arrow). The nodule was removed because of suspicion for cancer, and was found to be caused by infection with* C. neoformans. *Most cases of pulmonary cryptococcosis are asymptomatic, and it is not unusual to find nodules secondary to pulmonary cryptococcosis on chest x-rays taken for other reasons.*

in the management of cryptococcosis in many cases algorithms cannot be followed.

Amphotericin B therapy converted cryptococcal meningitis from a uniform fatal infection to one that is curable. Amphotericin B therapies prior to the AIDS epidemic reported therapeutic successes in 60–70 percent of patients (Sarosi et al. 1969). Recent studies have suggested that higher daily doses of amphotericin B may be more effective (deLalla et al. 1995) and with the use of lipid formulations of amphotericin B, such as AmBisome at 4 mg/kg/day, the use of a polyene as a single agent results in a reasonable treatment outcome (Leenders et al. 1997).

In early studies, flucytosine was used alone in the treatment of cryptococcal meningitis (Utz et al. 1972). However, enthusiasm for flucytosine as a single agent was quickly discouraged because of the rapid development of drug resistance. Fluconazole has outstanding CNS pharmacokinetics and has been used extensively in the treatment of cryptococcal meningitis (Stern et al. 1988; Berry et al. 1992; Saag et al. 1992; Yamaguchi et al. 1996). Because of concern about its slow CSF sterilization, its use has tended to occur after the burden of yeast has been reduced with other drug regimens. Despite its poor penetration into CSF, itraconazole has been used in the successful management of cryptococcal meningitis (Denning et al. 1989; Viviani et al. 1989). New extended-spectrum azoles such as voriconazole can treat cases of cryptococcosis (Perfect et al. 2003), but it is not certain how these azoles will improve on fluconazole treatment. The echinocandins, a new class of antifungal agents, do not appear to be effective in treatment of cryptococcal infections.

The most recent strategy for the management of cryptococcal meningitis uses a combination of antifungal drugs in sequence. Years of study have shown that conventional amphotericin B and flucytosine together are excellent for the initial management of infection (Utz et al. 1975; Bennett et al. 1979; Dismukes et al. 1987; Schmitt et al. 1988; Larsen et al. 1990; DeGans et al. 1992). The addition of flucytosine to amphotericin B helps sterilize the CSF quicker than amphotericin B alone or combinations of amphotericin B and fluconazole. It has also been associated with fewer cases of relapse compared to a single agent (Saag et al. 1999). A large comparative study in AIDS patients for the management of cryptococcal meningitis has also been adopted in the treatment of non-AIDS patients with cryptococcal meningitis (van der Horst et al. 1997; Pappas et al. 2001). The regimen used in this study was amphotericin B at 0.7 mg/kg/day and flucytosine 100 mg/kg/day for at least 2 weeks of induction therapy and then switching to oral fluconazole at 400–800 mg/day alone for 8 weeks. Ideally, a lumbar puncture would be performed after 2 weeks of therapy with extension of the amphotericin B therapy if the CSF cultures are still postive. After these 2.5–3 months of therapy, the fluconazole at 200–400 mg/day is continued for 6 months to a year in non-AIDS patients and in AIDS patients suppression therapy had been recommended for a lifetime prior to HAART. In the suppressive stage of treatment, there are data that suggest that the use of fluconazole may be better than itraconazole (Saag et al. 1999). With the advent of HAART and thus improvement in immunity with antiretroviral therapies, the need for lifelong suppression in patients who have reduced their viral load, increased their CD4 cells ($\geqslant$200 cells/ml), and been free of clinical cryptococcal disease for 1–2 years is being questioned. Recent studies have supported stopping fluconazole in this patient population where the underlying disease is being controlled with HAART (Martinez et al. 2000; Vibhagool et al. 2003).

The issue of discontinuing chronic suppressive therapy was evaluated by a retrospective observational study of 100 patients with a definitive diagnosis of cryptococcal meningitis who subsequently had CD4 counts above 100 cells/μL while receiving HAART (Mussini et al. 2004). Prior to discontinuation of chronic suppressive antifungal therapy, the median duration of HAART in this patient cohort was 26 months, the median duration of maintenance therapy was 33 months, and the median time the CD4 count had been above 100 cells/μL was one month. Forty-one patients had a positive serum cryptococcal antigen at the time maintenance therapy was discontinued. Over a median follow-up of 28 months, there were two relapses of cryptococcal meningitis and two cases of extrameningeal cryptococcosis. The relapse in one patient occurred at a CD4 count of 46 cells/μL, but the other three patients all had negative serum cryptococcal antigen test results at the time therapy was discontinued, and at the time of relapse or extrameningeal disease had undetectable HIV viral loads and CD4 counts above 100 cells/μL (two above 400 cells/μL). These data demonstrate that it may be possible to withdraw chronic suppressive therapy in select patients, but that there remains a small, but significant, risk for recurrence of cryptococcosis.

Site of infection

Unlike cryptococcal meningitis, pulmonary cryptococcosis has not been prospectively studied and most data come from retrospective examination of patient outcomes. Azoles such as fluconazole at 200–400 mg/day for 3–6 months are generally safe and effective (Dromer et al. 1996; Yamaguchi et al. 1996; Pappas et al. 2001). In fact, fluconazole can be used in the treatment of both symptomatic and asymptomatic patients with *C. neoformans* isolated from the lung or sputum. In seriously ill patients, the use of amphotericin B or the combination of amphotericin B plus flucytosine may be more attractive. Surgery has been recommended for a large CNS lesion (>3 cm) and lung abscesses with *C. neoformans*

var. *gattii*, but this strategy should only be followed on an individual case basis. Treatment of other sites of cryptococcal infection should be determined by their location and host factors. Amphotericin B-containing regimens should be considered as induction therapy when there is a high burden of yeasts such as during severe immune depression, but otherwise fluconazole is a reasonable choice.

Immune status of host

Every attempt to improve immunity of the host during treatment needs to be made. On a practical basis this may mean an attempt to reduce immunosuppressive agents, for instance, reduction of prednisone doses to 20 mg/day or less per day. Treatment with HAART can help reconstitute the immune cells of patients with HIV infection and should be encouraged in the management of cryptococcal meningitis, but the timing of a HAART regimen in relationship to stage of treatment remains uncertain. For instance, it is clear that a reconstitution syndrome can occur in the central nervous system or other sites when patients with cryptococcosis are started on HAART (Jenny-Avital and Abadi 2002). This syndrome is marked by evidence of sterile inflammation at this site of infection and this could add to new symptoms in the patient. In patients with increased intracranial pressure, the immune reconstitution may actually worsen symptoms and immune reconstitution syndrome may actually improve with the use of corticosteroid therapy to reduce symptomatic inflammation. Better guidance into what is the best time for HAART therapy in patients with cryptococcosis is needed, but it may be reasonable to start HAART after several months of antifungal therapy to control the initial yeast burden of infection.

Suppressive therapy

Relapse rates in AIDS patients with cryptococcal meningitis before HAART approached 50–60 percent when therapy was stopped within the first 6 months. Fluconazole suppressive therapy with 200 mg/day in AIDS patients has dramatically reduced these numbers to less than 5 percent (Bozette et al. 1991) and it is probably better than intermittent intravenous amphotericin B and/or daily suppression with itraconazole (Powderly et al. 1992). Since non-AIDS patients also relapse (10–15 percent) in the first 6 months after therapy is stopped, this suppressive strategy is similar to the AIDS patients' strategy with 6–12 months of fluconazole after induction therapy being used. In AIDS patients, suppressive therapy has been used for a lifetime, but recent data have studied the discontinuation of drugs after 1–2 years in those with a satisfactory response to HAART (Martinez et al. 2000; Vibhagool et al. 2003).

Role of intracranial pressure

Patients with a high burden of yeasts and polysaccharide antigen can develop increased intracranial pressure before, during, or after treatment (Denning et al. 1991b; Graybill et al. 2000). In this syndrome of early increased intracranial pressure, the patient can suddenly develop systemic hypertension, decreased sensorium, cranial neuropathies, visual loss, worsening headaches, and mental confusion. It is suggested that this elevated pressure is related to reduced CSF resorption, brain edema, and CSF outflow resistance. This increased pressure may respond to CSF withdrawal techniques (lumbar–peritoneal shunts, repeated lumbar taps) (Van Gemert and Vermeulen 1991), but the preciseness of management for this life-threatening complication remains unclear. On the other hand, development of classic noncommunicating hydrocephalus weeks or months after treatment is probably related to inflammation and scar tissue from the original infection and should respond to a ventriculoperitoneal (VP) shunt. A VP shunt can be placed successfully while cryptococcal meningitis is being effectively treated. However, shunts should not be placed until adequate antifungal treatment has begun (Yadav et al. 1988; Ingram et al. 1993).

Antigen titers

CSF polysaccharide antigen titers generally report the burden of yeasts at initial diagnosis, and high antigen titers do predict poor prognosis. However, in an individual patient the reliability of following antigen titers to guide therapy is unclear (Powderly et al. 1994), and thus it is difficult to use titer changes during therapy to make clinical decisions.

Cytokines and specific antibodies

Disseminated cryptococcosis generally occurs during an episode of immunosuppression. Granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage colony-stimulating factor (M-CSF), IL-2, IL-12, and interferon-gamma can positively interact with host cells to inhibit or kill cryptococci. Both GM-CSF and interferon-gamma have been examined in open human trials, but it remains uncertain whether these biological modifiers will have a positive impact on the outcome of this infection. Interferon-gamma treatment has been studied prospectively; there was a trend toward a faster reduction in yeast counts in the CSF but no impact on outcome. Specific monoclonal antibodies and serum therapy have a positive effect on the prevention and treatment of experimental cryptococcosis. Early safety studies with a monoclonal antibody have been completed in humans, but efficacy data with the use of antibodies are lacking. It remains important to continue examination on the impact of biolo-

gical enhancers and strategies for management of infection since there is still a 10–25 percent acute mortality rate for cryptococcal meningitis during early therapies even in medically advanced countries.

PROGNOSTIC FACTORS

The most important prognostic factor for a patient with cryptococcosis is the nature of their underlying illnesses. Certainly, those patients with underlying malignancies or AIDS have a much poorer prognosis than those patients with no apparent risk factors for cryptococcosis. In one comparison of patients with cryptococcal meningoencephalitis, patients with malignancies as an underlying risk factor actually had a much shorter median survival rate than patients with AIDS (2 versus 9 months) (White et al. 1992), and this observation was made before the use of HAART, which even further improves the survival of patients with AIDS and cryptococcosis.

In patients without AIDS, several clinical features have been identified which correlate with treatment failure (Diamond and Bennett 1974; Bennett et al. 1979; Dismukes et al. 1987). Patients who have died during therapy have been more likely to have presented with:

- positive India ink examinations of the CSF
- CSF white blood cell counts of less than 20 cells/mm^3
- initial CSF or serum cryptococcal antigen titers of more than 1:32
- extraneural sites of infection
- high opening pressures (>350 mmH_2O) on lumbar puncture (Diamond and Bennett 1974).

Patients who relapsed after treatment have been characterized by:

- persistently low CSF glucose concentrations after 4 weeks of therapy
- low initial CSF white blood count, ⩾ post-treatment CSF, or serum antigen titers of 1:8 or more
- treatment with corticosteroids with at least 20 mg prednisone or its equivalent daily after completion of therapy (Diamond and Bennett 1974).

In patients without AIDS as an underlying risk factor, the following factors predicted a favorable response:

- normal mental status, headache, CSF white blood count over 20 cells/mm^3
- absence of another underlying disease
- negative CSF India ink preparations (Dismukes et al. 1987).

Although these observations were made more than 15–25 years ago, they still likely identify patients with a high burden of yeasts, poor mental status, difficult-to-treat underlying disease on presentation, and risk for failure of treatment.

In patients with AIDS as a risk factor, significant pretreatment predictors of death during therapy include:

- abnormal mental status
- a CSF antigen titer of more than 1:1 024
- a CSF white blood count of less than 20 cells/mm^3 (Saag et al. 1992).

Diastolic hypertension has also been associated with earlier death in these patients (Fan-Havard et al. 1992), and this finding is probably reflective of increased intracranial pressure. The AIDS patient with cryptococcal meningitis at highest risk for complications has:

- high burden of yeasts
- poor inflammatory response
- increased intracranial pressure ⩾350 mmH_2O.

PREVENTION

Trying to prevent cryptococcosis in the general population is an unrealistic task given its rarity. However, in certain high-risk populations, antifungal prophylaxis is a consideration. Some data have been collected from patients with AIDS who were given chronic fluconazole for prophylaxis (Nightingale et al. 1992). Patients receiving fluconazole 200 mg/day had cryptococcosis rates of 1 percent over 35 months, compared with patients given topical clotrimazole who had rates of 7 percent (Powderly et al. 1995). However, general recommendations for fluconazole prophylaxis in patients with AIDS can be made only after very careful consideration of costs, impact on survival, prevalence of the infection, and the potential development of azole resistance in other fungal species. It is rarely considered today in the era of HAART.

Immunization is an attractive form of preventing cryptococcosis. A cryptococcal glucuronoxylomannan tetanus toxoid conjugate vaccine was developed, and it appeared to be highly immunogenic in murine models (Devi et al. 1991). There are now several *C. neoformans* immunogenic proteins in which genes have been cloned and recombinant proteins made. Thus progress toward vaccine development is being made. Trials in humans have not yet been done with any product, but it seems that, for patients at highest risk for cryptococcosis, any vaccine will have to be administered at a time when their immune systems are competent enough to make a protective response. Without a standardized skin test, it is more difficult to determine who is at risk and the magnitude of potential need.

Systemic zygomycosis

DAVID H. ELLIS

Introduction	1	Laboratory diagnosis	17
Etiologic agents of medical importance	3	Treatment (management/therapy)	19
Host responses	14	References	20

INTRODUCTION

The Zygomycetes are a class of relatively primitive, fast growing, widely distributed, terrestrial fungi which are largely saprobic on plant debris and in soil. Many species are common environmental contaminants, often causing food spoilage; some are sources of food in the Orient; and a few are pathogens of plants, insects, and, more rarely, of humans. Several species are thermophilic, capable of growing at well over 40°C. Hyphae are coenocytic and mostly aseptate, making them clearly distinguishable from those of other filamentous fungi. Although the absence of hyphal cross-walls or septa facilitates rapid growth and sporulation by allowing the uninhibited absorption and translocation of nutrients, together with cellular organelles between growth sites, it is also a significant disadvantage in that hyphal elements are prone to physical damage and subsequent death. By comparison, when septate hyphae, which are typically found in higher fungi belonging to the Basidiomycetes and Ascomycetes, are damaged, the pores between adjacent compartments are plugged, thus preventing death of the whole hyphal strand.

Thus, in human cases of zygomycosis, reliable culture identification of the causative fungus is made in less than 50 percent of the cases reported in the literature (Scholer et al. 1983). Asexual reproduction is by nonmotile sporangiospores, by modified sporangial units functioning as conidia, or by true conidia (Hesseltine and Ellis 1973). Sexual reproduction is isogamous through the formation of zygospores. However, most isolates appear to be heterothallic, requiring mating by two distinct strains for the formation of zygospores. Thus, in pure culture the sexual or zygosporic state is of limited taxonomic value, although recent mating experiments, leading to the formation of zygospores, have been used to confirm the identity of three zygomycetous fungi isolated from clinical specimens (Weitzman et al. 1995). Occasionally, resting spores known as azygospores, which develop from a single gametangium without any evidence of sexual fusion, may also be observed in some species (Benjamin 1979). At present, the classification and identification of zygomycetous fungi are based primarily on the asexual or anamorphic state, which is characterized by the production of sporangia and sporangiospores.

Sporangiospores are distinguished from other asexual fungal spores, in that they are cleaved out of the cytoplasmic contents of the sporangium without the wall of the sporangium being directly involved in the formation of the spore wall (Benjamin 1979). Other asexual reproductive structures occasionally observed in some species are chlamydoconidia and yeast-like blastoconidia. Chlamydoconidia are thick-walled resting structures formed endogenously within the hyphae. Yeast-like growth usually occurs only under specific culture conditions, especially anaerobiosis or high glucose concentrations, and has been reported in species from a number of genera, including *Cokeromyces*, *Mucor*, and *Rhizomucor* (Benjamin 1979). As a result of the above characteristics, the Zygomycetes, as a class, have long been considered a rather natural group. This grouping has been supported by the composition of the cell wall which is chitosan–chitin in nature (Hesseltine and Ellis 1973) and by molecular evidence (Kwon-Chung 1994). More recent molecular phylogeny studies have provided

strong support for the monophyly of the Mucorales, with the exception of *Mortierella* spp., which appear to be misclassified within the Mucorales (Voigt et al. 1999). Accordingly a new order, the Mortierellales, has been proposed to accommodate *Mortierella* (Cavalier-Smith 1998; Voigt and Wostemeyer 2001). Based on the 18S gene tree topology, *Absidia corymbifera* and *Rhizomucor variabilis* also appear to be misplaced taxonomically. *A. corymbifera* is strongly supported as a sister group of the *Rhizomucor miehei–Rhizomucor pusillus* clade, while *R. variabilis* is nested within *Mucor* (Voigt et al. 1999). To date, some 870 species of the Zygomycetes have been described (Kirk et al. 2001). Until 1979, the Zygomycetes were divided into two orders: the Mucorales and the Entomophthorales (Onions et al. 1981). Hesseltine and Ellis (1973) gave a comprehensive key to the groups and genera and accepted 14 families in the Mucorales. Based on phylogenetic relationships, Benjamin (1979), O'Donnell (1979), and Jefferies (1985) produced a new classification of the Zygomycetes at ordinal level, creating seven orders and 30 families. Currently 10 orders and 32 families are recognized (Kirk et al. 2001); with three orders containing genera and species of medical importance: the Mucorales, Mortierellales, and Entomophthorales. The term 'zygomycosis' is used in this chapter to describe any infection caused by a member of the Mucorales or Mortierellales. However, it should be noted that some authors still prefer to use the term 'mucormycosis' to describe mycoses caused by members of the Mucorales and Mortierellales and entomophthoromycosis (or entomophthoramycosis – the spelling used seems to depend upon the author) to describe mycoses caused by species belonging to the Entomophthorales. In general, fungi in the order Mucorales cause the more severe forms of disease, whereas those in the order Entomophthorales cause disease of the nasal mucosa and subcutaneous tissue (Goodman and Rinaldi 1991). Recent reviews of the Zygomycetes of medical interest have been made by Ribes et al. (2000), Schipper and Stalpers (2003), and Dromer and McGinnis (2003).

Mucorales

The Mucorales (commonly called bread or pin molds) consist of fungi that reproduce asexually by means of nonmotile sporangiospores borne in sporangia (multispored), merosporangia (spores aligned in rows), sporangiola (containing few spores), or as one-spored sporangia or conidia. Sporangia generally have a central columella, which may extend below the sporangium to form a funnel-shaped apophysis. Several species also develop stolons and rhizoids.

Most of the species known to cause human or animal infections belong to a few genera within the family *Mucoraceae*, and are readily recognizable by their rapid growth rate, filling a Petri dish within 3–5 days, and their characteristic appearance, colonies usually being loosely floccose and of a gray or brownish-gray color (Table 1). These include members of the genera *Absidia*, *Apophysomyces*, *Mucor*, *Rhizomucor*, and *Rhizopus*. *Rhizopus oryzae* (*arrhizus*) is the most frequent infectious agent reported, followed by *Rhizopus microsporus* var. *rhizopodiformis*, *Absidia corymbifera*, and *Rhizomucor pusillus* (Scholer et al. 1983). These four species account for more than 80 percent of culture-proven cases of zygomycosis. Other mucoraceous species reported less frequently include *R. microsporus* var. *microsporus*, *Mucor ramosisimus*, *Mucor circinelloides*, *Mucor indicus*, and *Apophysomyces elegans*. Members of several other genera belonging to other families, such as *Cunninghamella bertholletiae* (*Cunninghamellaceae*), and *Saksenaea vasiformis* (*Saksenaeceae*), are also occasionally reported.

Mortierellales

This is a newly created order to accommodate a single family, the *Mortierellaceae* (Cavalier-Smith 1998). All structures are generally more delicate than in the Mucorales and the sporangia have no columellae and are split into numerous, few, or single spores. *Mortierella*

Table 1 *Families and genera of the Mucorales of medical importance*

Family	Genera	Key identification features
Mucoraceae	*Absidia*, *Apophysomyces*, *Mucor*, *Rhizomucor*, *Rhizopus*	Multispored sporangia with columella which may or may not show an apophysis. Sporangia may be globose, pyriform, or ellipsoidal in shape
Cunninghamellaceae	*Cunninghamella*	Single-spored, globose to ovoid, echinulate sporangiola (conidia) borne on globose to clavate fertile vesicles
Saksenaeaceae	*Saksenaea*	Flask-shaped sporangia with columella and simple, darkly pigmented rhizoids
Syncephalastraceae	*Syncephalastrum*	Cylindrical merosporangia with spores in one row borne on globose vesicles
Thamnidiaceae	*Cokeromyces*	Dimorphic with yeast growth at 37°C, sporangiola with few spores borne on long recurved pedicles arising from a fertile vesicle

wolfii is probably the only species pathogenic to animals (Zycha et al. 1969; Domsch et al. 1980; de Hoog and Guarro 1995), although Scholz and Meyer (1965) have reported a case of pulmonary infection in cattle caused by *Mortierella polycephala*.

ETIOLOGIC AGENTS OF MEDICAL IMPORTANCE

By definition, all pathogenic zygomycotic species will grow at 37°C, with the possible exception of the *M. circinelloides* group. Thus occasional reports of infections caused by species unable to grow at temperatures above 35°C must be regarded as questionable. Usually laboratory incubation temperatures range between 26 and 35°C; however, growth temperature studies at 40 or 45°C can also be helpful. Most isolates are heterothallic, i.e. zygospores are absent, so identification of those species is based primarily on sporangial morphology. This includes the arrangement and number of sporangiospores, shape, color, presence or absence of columellae and apophyses, as well as the arrangement of the sporangiophores and the presence or absence of rhizoids. Tease mounts are best, using a drop of 95 percent alcohol as a wetting agent to reduce air bubbles. There are very few molecular techniques currently in use for the identification of zygomycetes, most studies have been directed at phylogeny. (For detailed descriptions of species, keys to taxa, and additional information, see Hesseltine and Ellis 1964, 1966; Ellis and Hesseltine 1965, 1966; Nottebrock et al. 1974; O'Donnell 1979; Domsch et al. 1980; McGinnis 1980; Onions et al. 1981; Scholer et al. 1983; Samson et al. 1995; Goodman and Rinaldi 1991; Ribes et al. 2000; Schipper and Stalpers 2003.)

Absidia corymbifera (Cohn) Saccardo & Trotter

The genus *Absidia* is characterized by a differentiation of the hyphae into arched stolons bearing more or less verticillate sporangiophores in the raised part (internode), and rhizoids formed at the point of contact with the substrate (at the node). This feature separates the species of *Absidia* from those of the genus *Rhizopus*, where the sporangia arise from the nodes and are, therefore, found opposite the rhizoids. The sporangia are relatively small, globose, pyriform, or pear shaped, and are supported by a characteristic funnel-shaped apophysis. This distinguishes the genus *Absidia* from the genera *Mucor* and *Rhizomucor*, which have large, globose sporangia without an apophysis. *Absidia* currently contains 21 mostly soil-borne species (Zycha et al. 1969; Domsch et al. 1980; Schipper 1990; Schipper and Stalpers 2003). *A. corymbifera* is the only species of *Absidia* known to cause disease in humans and animals. *Absidia ramosa*, previously reported as a pathogenic species, has now been reduced to synonymy with *A. corymbifera* (Nottebrock et al. 1974; Scholer et al. 1983).

A. corymbifera (synonym: *A. ramosa*) is a relatively rare agent of human zygomycosis (Kwon-Chung and Bennett 1992); it is more often reported as an animal pathogen (Smith 1989; Jensen et al. 1989, 1990; Jensen 1992; Knudtson and Kirkbride 1992; Guillot et al. 2000). However, it was probably responsible for the first reported case of human pulmonary zygomycosis (Furbringer 1876) and it is occasionally reported from this site (the lungs) (Murphy and Bornstein 1950; Darja and Davy 1963; Lake et al. 1988; Leleu et al. 1999). However, *A. corymbifera* is most often associated with cutaneous infections in both immunocompetent patients, often following localized trauma (Roger et al. 1989; Marshall et al. 1997; Scalise et al. 1999; Seguin et al. 1999; Narain et al. 2001; Thami et al. 2003), and immunosupressed patients, including bone marrow transplant (Hagensee et al. 1994; Jantunen et al. 1996; Leong et al. 1997; Leleu et al. 1999; Paterson et al. 2000), idiopathic aplastic anemia (Cloughley et al. 2002), neonates (Amin et al. 1998; Buchta et al. 2003), and AIDS patients (Chavanet et al. 1990; Hopwood et al. 1992). Lopes et al. (1995) described an unusual case of cutaneous infection from a leukemic patient, which probably resulted from latent osteomyelitis. It has also been reported as the causative agent of meningitis that followed a penetrating head injury (Mackenzie et al. 1988), renal infection in intravenous drug-using AIDS patients (Smith et al. 1989; Torres-Rodriguez et al. 1993), and rhinocerebral infection in neutropenic patients (Manso et al. 1994; Ryan et al. 2001). *A. corymbifera* has a worldwide distribution mostly in association with soil and decaying plant debris (Domsch et al. 1980).

Colonies are fast growing, floccose, white at first, becoming pale gray with age, and up to 1.5 cm high. Sporangiophores are hyaline to faintly pigmented, simple or sometimes branched, arising solitary from the stolons, in groups of three, or in whorls of up to seven. Rhizoids are very sparingly produced and may be difficult to find without the aid of a dissecting microscope to examine the colony on the agar surface. Sporangia are small (10–40 μm in diameter) and are typically pyriform in shape with a characteristic conical columella and pronounced apophysis, often with a short projection at the top (Figure 1). Sporangiospores vary from subglobose to oblong–ellipsoidal (3.0–7.0×2.5–4.5 μm) and are hyaline to light-gray and smooth walled. Zygospores formed by compatible mating strains are reddish-brown, thick walled (60–100×45–80 μm) and have flat projections and one to three equatorial ridges. Isolates are thiamine dependent and have an optimum growth temperature of 35°C, with a maximum of 48–52°C. Key laboratory diagnostic features are growth at 40°C and the formation of small pyriform sporangia with characteristic conical columellae and pronounced apophyses.

Figure 1 Absidia corymbifera *showing a typical pyriform-shaped sporangium with a conical columella and pronounced apophysis. Magnification ×330*

(For additional taxonomic descriptions, see Ellis and Hesseltine 1965; Hesseltine and Ellis 1966; Nottebrock et al. 1974; O'Donnell 1979; Domsch et al. 1980; McGinnis 1980; Scholer et al. 1983; Schipper 1990; Samson et al. 1995; de Hoog et al. 2000; Schipper and Stalpers 2003.)

Apophysomyces elegans Misra, Srivastava & Latas

The genus *Apophysomyces* was erected by Misra et al. (1979) to accommodate a new mucoraceous fungus with prominent funnel-shaped apophyses, which they named *A. elegans*. It is readily distinguishable from other zygomycetes of medical importance, especially the morphologically similar, strongly apophysate pathogen *Absidia corymbifera*. *A. elegans* has sporangiophores with distinctive funnel- or bell-shaped apophyses and hemispherical columellae, a conspicuous pigmented subapical thickening which constricts the lumen of the sporangiophore below the apophysis, and distinctive foot cells. However, *A. elegans* may resemble *S. vasiformis* in gross colony morphology and in its failure to sporulate on routinely used media (Ellis and Ajello 1982; Padhye and Ajello 1988).

A. elegans is an emerging human pathogen of apparently immunocompetent patients and is usually associated with invasive soft tissue infections complicated by burns or wounds contaminated by soil (Winn et al. 1982; Wieden et al. 1985; Newton et al. 1987; Cooter et al. 1990; Huffnagle et al. 1992; McGinnis et al. 1993; Weinberg et al. 1993; Holland 1997; Burrell et al. 1998; Kimura et al. 1999; Page et al. 2001; Blair et al. 2002). Other reports include infections of the kidney and bladder (Lawrence et al. 1986; Okhuysen et al. 1994; Naguib et al. 1995), abdominal wall (Lakshmi et al. 1993), rhinocerebral infection (Brown et al. 1998; Garcia-Covarrubias et al. 2001), and osteomyelitis (Eaton et al. 1994; Meis et al. 1994). Interestingly, most cases occur in apparently immunocompetent patients, indicating that traumatic implantation of the fungus through the skin is the most important predisposing factor. *A. elegans* is a soil fungus with a tropical to subtropical distribution. It was initially isolated from soil samples collected from a mango orchard in northern India (Misra et al. 1979) and subsequently from soil in northern Australia (Cooter et al. 1990).

Colonies are fast growing, white becoming creamy white to buff with age, downy with no reverse pigment, and are composed of broad, sparsely septate (coenocytic) hyphae typical of a zygomycetous fungus. Sporangiophores are unbranched, straight or curved, slightly tapering towards the apex, up to 200 μm long, 3–5 μm in width near the apophysis, and hyaline when young but developing, as the culture ages, a sepia to brown pigmentation and a conspicuous subapical thickening 10–16 μm below the apophysis (Figure 2). Sporangiophores arise at right angles from the aerial hyphae and often have a septate basal segment resembling the 'foot cell' commonly seen in *Aspergillus* spp. Rhizoids are thin walled, subhyaline, and predominantly unbranched. Sporangia are multispored, small (20–50 μm in diameter), typically pyriform in shape, hyaline at first, sepia colored when mature, columellate and strongly apophysate (Figure 2). Columellae are hemispherical in shape and the apophyses are distinctively funnel or

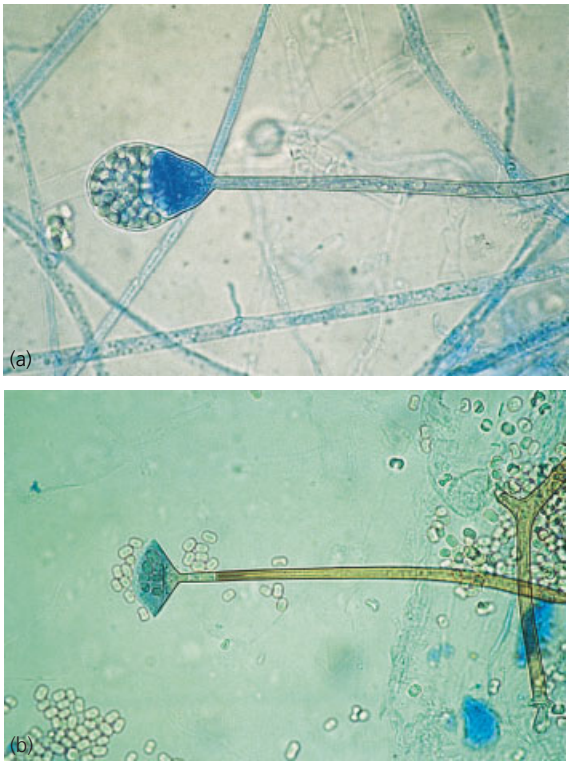

Figure 2 Apophysomyces elegans*:* **(a)** *young sporangium;* **(b)** *mature sporangium showing distinctive funnel-shaped apophyses and a conspicuous pigmented subapical thickening below the apophysis. Magnification ×495*

bell shaped. Sporangiospores are smooth walled, mostly oblong, occasionally subglobose (3–4×5–6 μm), and subhyaline to sepia *en masse*. Good growth occurs at 26, 37 and 42°C. Key laboratory diagnostic features include rapid growth at 42°C (thermotolerant), and the formation on nutrient-deficient media of characteristic 'cocktail glass' sporangia. (For additional taxonomic descriptions, see Misra et al. 1979; Ellis and Ajello 1982; Wieden et al. 1985; Lawrence et al. 1986; Padhye and Ajello 1988; Cooter et al. 1990; McGinnis et al. 1993; de Hoog et al. 2000.)

Cokeromyces recurvatus Poitras

C. recurvatus is the type species of the genus *Cokeromyces* and is usually found in soil or isolated from rodent or lizard dung (Shanor et al. 1950; Benny and Benjamin 1976). It has been reported on several occasions from humans as a colonizer of the vagina (Rippon and Dolan 1979; McGough et al. 1990; Kwon-Chung and Bennett 1992; Kemna et al. 1994) and once from the urinary bladder (Axelrod et al. 1987). *C. recurvatus* has also been reported as causing severe diarrhea in bone marrow transplant recipients (Alvarez et al. 1995; Tsai et al. 1997) and pleuritis and peritonitis in a patient with a ruptured peptic ulcer (Munipalli et al. 1996). Its validity as a human pathogen is, however, doubtful because there has not been any evidence of tissue invasion in any cases. *C. recurvatus* is one of the few zygomycetous fungi that exhibits thermal dimorphism by growing at 37°C in a yeast-like form characterized by the development of large, spherical cells, bearing one to many buds, similar in appearance to those of *Paracoccidioides brasiliensis*, but growing as a mold when incubated at lower temperatures.

Colonies grow moderately at 25°C and are flat, radially wrinkled, tan to brown, becoming grayish with the production of sporangiospores. Sporangiophores are mostly unbranched, 9 μm wide and produce terminal vesicles up to 30 μm in diameter; rhizoids are absent. Sporangiola have few spores, and are globose to obovoid, with a columella, but no apophysis; they are borne terminally on long, recurved, and contorted pedicles which arise from the fertile vesicle formed at the apex of the sporangiophore. Sporangiospores are smooth walled and ovoid to ellipsoid in shape (2.5×4.5 μm). Zygospores are produced in abundance (homothallic) and are dark brown, globose (33.5–54.5 μm in diameter) with rough walls resulting from sharply pointed projections. Isolates readily convert from mold-like to yeast-like colonies when incubated at 35–37°C on enriched media such as brain heart infusion agar with 5 percent sheep blood. *C. recurvatus* has a maximum growth temperature of 42°C, is thiamine dependent, has a positive assimilation of nitrate, negative assimilation of sucrose, negative fermentation of glucose and is sensitive to cycloheximide (Kemna et al. 1994). Key features include dimorphic growth as a yeast at 37°C, sporangiola borne terminally on long recurved stalks, and the development of abundant zygospores at 25°C. (For further information see Zycha et al. 1969; Goodman and Rinaldi 1991; Kwon-Chung and Bennett 1992; Kemna et al. 1994; de Hoog et al. 2000.)

Cunninghamella bertholletiae Stadel

The genus *Cunninghamella* is characterized by white to gray, rapidly growing colonies, producing erect, straight, branching sporangiophores. These sporangiophores end in globose or pyriform vesicles from which several one-celled, globose to ovoid, echinulate or smooth-walled sporangiola develop on swollen denticles. Chlamydoconidia and zygospores may also be present. *Cunninghamella* species are mainly soil fungi of the Mediterranean and subtropical zones, and they are only rarely isolated in temperate regions. The genus now contains seven species, with *C. bertholletiae*, the only one known to cause disease in humans and animals (Domsch et al. 1980).

Once again, there has been some confusion as to the correct name of this zygomycete. Many medical mycologists (McGinnis 1980; Weitzman 1984; Rippon 1988) preferred the name *C. bertholletiae* because of the thermophilic nature of the human isolates that grow at temperatures as high as 45°C. However, Samson (1969) and Domsch et al. (1980) preferred the name *Cunninghamella elegans* and Lunn and Shipton (1983) went further and reduced *C. elegans* (*C. bertholletiae*) to a variety of *Cunninghamella echinulata*, i.e. *C. echinulata* var. *elegans*. However, *C. bertholletiae* is currently the most acceptable name; *C. elegans* differs by having purely gray colonies and by not growing at temperatures above 40°C (Weitzman and Crist 1979; de Hoog et al. 2000).

C. bertholletiae is a common soil fungus found throughout the temperate regions of the world. It is a rare cause of zygomycosis in humans, often associated with traumatic implantation (Boyce et al. 1981) and immunosuppression (Robinson et al. 1990). Pulmonary infections are being reported with increasing frequency in cancer patients (Kwon-Chung et al. 1975; Kiehn et al. 1979; Ventura et al. 1986; Reed et al. 1988; Maloisel et al. 1991; Cohen-Abbo et al. 1993; Dermoumi 1993; Kontoyianis et al. 1994; Mazade et al. 1998; Rickerts et al. 2000). Reports of pulmonary infection in immunocompetent patients are rare (Zeilender et al. 1990). Disseminated disease has been reported by Sands et al. (1985) and Iwatsu et al. (1990), and rare cases of rhinocerebral infection (Brennan et al. 1983) and sinusitis (Ng et al. 1994) have also been reported. Infections have also been reported in association with desferrioxamine therapy (Rex et al. 1988; Sane et al. 1989; Maloisel et al. 1991), transplant recipients (Kolbeck et al. 1985; Nimmo et al. 1988; Darrisaw et al. 2000; Garey et al. 2001; Zhang et al. 2002), and in AIDS patients (Mostaza et al. 1989).

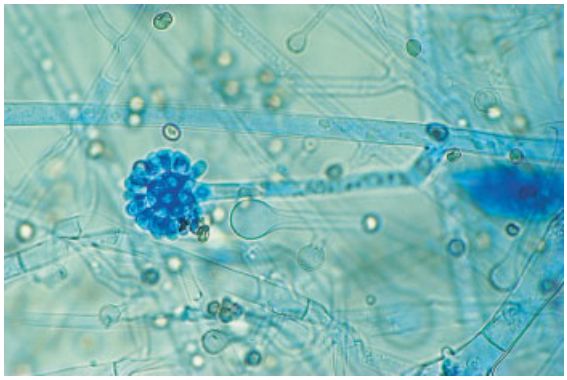

Figure 3 Cunninghamella bertholletiae*: microscopic morphology showing the formation of single-celled sporangiolas from a swollen vesicle. Magnification ×495*

Colonies are very fast growing, white at first, but becoming rather dark gray and powdery with development. Sporangiophores are up to 20 μm wide, straight, with verticillate or solitary branches. Vesicles are subglobose to pyriform, with the terminal ones being up to 40 μm and the lateral ones 10–30 μm in diameter. Sporangiola are globose (7–11 μm diameter), ellipsoidal (9–13×6–10 μm), verrucose or short echinulate, hyaline singly but brownish *en masse* (Figure 3). Temperature is at optimum 25–30°C and has a maximum up to 50°C. Key features include growth at 40°C and the presence of one-celled, globose to ovoid, echinulate 'conidia' borne on terminal or lateral globose to clavate fertile vesicles. (For additional information see Samson 1969; Weitzman and Crist 1979, 1980; Domsch et al. 1980; McGinnis 1980; Lunn and Shipton 1983; Weitzman 1984; Sands et al. 1985; Iwatsu et al. 1990; de Hoog et al. 2000.)

Mortierella wolfii Mehrotra & Baijal

The genus *Mortierella* has now been placed in a separate order, the Mortierellales (Cavalier-Smith 1998), and is characterized by gray to yellowish-grey, rapidly growing colonies, often spreading in overlapping 'waves' or lobes, which produce small delicate sporangia lacking a columella, on simple or branched sporangiophores (Figure 4). Sporangia may be one- or multispored and a collarette is typically left after the sporangial wall dissolves. Sporangiospores are one celled, globose to ellipsoidal, and chlamydoconidia may also be present. *Mortierella* spp. are common soil fungi and the genus contains about 90 recognized species; however, *M. wolfii* is probably the only species pathogenic to animals (Zycha et al. 1969; Domsch et al. 1980; de Hoog et al. 2000), although Scholz and Meyer (1965) have reported a case of pulmonary infection in cattle caused by *Mortierella polycephala*.

M. wolfii is an important causal agent of bovine mycotic abortion, pneumonia, and systemic mycosis in Australia, Europe, New Zealand, and the USA (di Menna et al. 1972; Carter et al. 1973; Wohlgemuth and Knudtson 1977; MacDonald and Corbel 1981; Neilan et al. 1982; Komoda et al. 1988; Smith 1989; Knudtson and Kirkbride 1992; Done et al. 1994; Johnson et al. 1994; Uzal et al. 1999). Confirmed human infections have not been documented. *M. wolfii* has also been isolated from soil, rotten silage, hay, and coal spoil tips (Mehrotra and Baijal 1963; Austwick 1965). Seviour et al. (1987) have described a specialized medium, silage extract agar, to stimulate sporulation of isolates of *M. wolfii*.

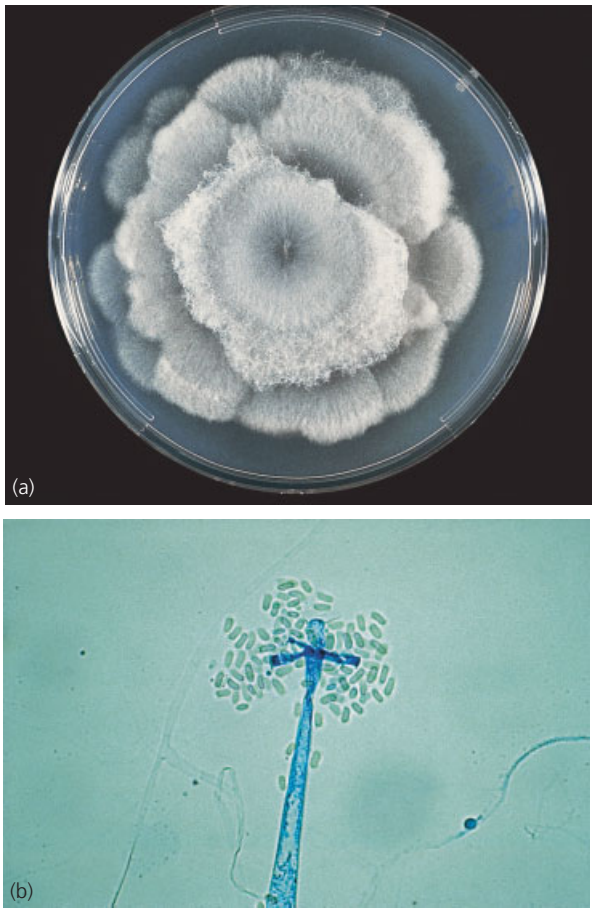

Figure 4 Mortierella wolfii*: **(a)** culture showing typical lobed growth pattern; **(b)** sporangium with acrotonous (terminal) branches. Magnification ×330*

Cultures are fast growing, white to grayish-white, downy, often with a broadly zonate or lobed (rosette-like) surface appearance, and no reverse pigment. Sporangiophores are typically erect, delicate, 80–250 μm in height, 6–20 μm wide at the base, arising from rhizoids or bulbous swellings on the substrate hyphae, and terminating with a compact cluster of short acrotonous (terminal) branches. Sporangia are usually 15–48 μm in diameter, with transparent walls, and a conspicuous collarette is usually present after dehiscence of the sporangiospores (Figure 4). Columellae are generally lacking and sporangiospores are single-celled,

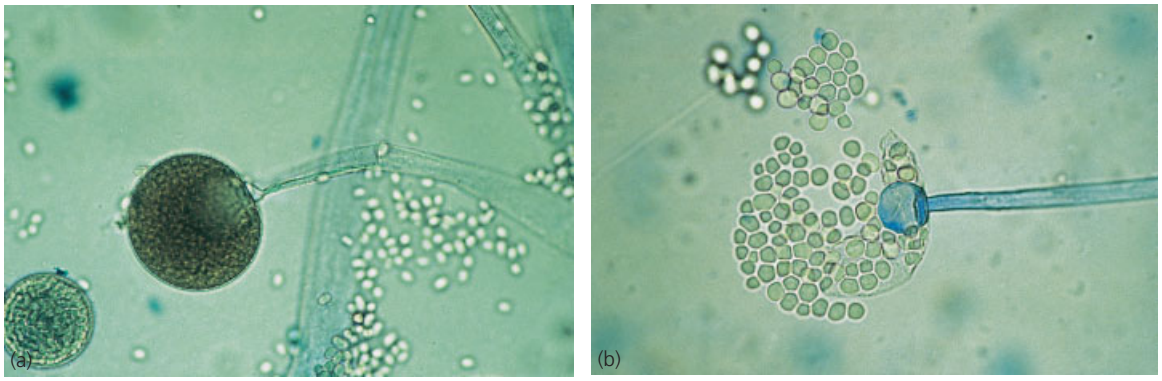

Figure 5 Mucor *species:* **(a, b)** *sporangia, columella and sporangiospores. Magnification ×495*

short–cylindrical, 6–10×3–5 μm, with a double membrane. Chlamydoconidia with or without blunt appendages (ameba-like) may be present. Zygospores have not been observed. Isolates grow well at 40–42°C, with a maximum of 48°C. Key features include rapid growth at 40°C (thermotolerant) and characteristic delicate acrotonous branching sporangia without columellae. (For additional information, see Mehrotra and Baijal 1963; Zycha et al. 1969; Domsch et al. 1980; Seviour et al. 1987; de Hoog et al. 2000.)

Mucor species

The genus *Mucor* can be differentiated from *Absidia*, *Rhizomucor*, and *Rhizopus* by the absence of stolons and rhizoids. Colonies are very fast growing, cottony to fluffy, white to yellow, becoming dark gray, with the development of sporangia. Sporangiophores are erect, simple or branched, forming large (60–300 μm in diameter), terminal, globose to spherical, multispored sporangia, without apophyses and with well-developed subtending columellae (Figure 5). A conspicuous collarette (remnants of the sporangial wall) is usually visible at the base of the columella after sporangiospore dispersal. Sporangiospores are hyaline, gray or brownish, globose to ellipsoidal, and smooth walled or finely ornamented. Chlamydoconidia and zygospores may also be present. The genus contains about 50 recognized taxa, many of which have widespread occurrence and are of considerable economic importance (Zycha et al. 1969; Schipper 1978a; Domsch et al. 1980). However, only a few thermotolerant species are of medical importance and human infections are only rarely reported (Table 2). Most infections reported list *M. circinelloides* and similar species such as *M. indicus* (*M. rouxii*), *Mucor ramosissimus*, and *Mucor amphibiorum* as the causative agents. However, *Mucor hiemalis* and *Mucor racemosus* have also been reported as infectious agents, although their inability to grow at temperatures above 32°C raises doubt as to their validity as human pathogens and their pathogenic role may be limited to cutaneous infections (Scholer et al. 1983; Goodman and Rinaldi 1991; Kwon-Chung and Bennett 1992; de Hoog et al. 2000). Key laboratory diagnostic features are the presence of large, spherical, non-apophysate sporangia with pronounced columellae and conspicuous collarettes after sporangiospore dispersal. (For additional information, see Schipper 1978a; Domsch et al. 1980; McGinnis 1980; Onions et al. 1981; Scholer et al. 1983; Rippon 1988; Goodman and Rinaldi 1991; Samson et al. 1995; de Hoog et al. 2000; Schipper and Stalpers 2003.)

MUCOR AMPHIBIORUM SCHIPPER

This species has been reported as the causative agent of zygomycosis in several amphibia (Frank et al. 1974; Schipper 1978a; Speare et al. 1994, 1997; Berger et al. 1997) and in free-living platypuses (*Ornithorhynchus anitinus*) (Obendorf et al. 1993; Connolly et al. 2000). Human infections have not been reported. Colonies are

Table 2 *Maximum temperature of growth for the reported pathogenic species of* Mucor

Species	Maximum temperature (°C)	Pathogenicity
M. amphibiorum	36	Animals, principally amphibians
M. circinelloides	36–40	Animals, occasionally humans
M. hiemalis	30	Questionable cutaneous infections only
M. indicus	42	Humans and animals
M. racemosus	32	Questionable
M. ramosissimus	36	Humans and animals

grayish-brown, slightly aromatic, and do not grow at 37°C (maximum temperature for growth is 36°C). Sporangiophores are hyaline, erect, and mostly unbranched, rarely sympodially branched. Sporangia are dark brown, up to 75 μm in diameter, and are slightly flattened with a diffluent membrane. Columellae are subglobose to ellipsoidal or pyriform, up to 60×50 μm, with small collars. Sporangiospores are smooth walled, spherical, and 3.5–5.5 μm in diameter. Zygospores, when formed by compatible mating types, are spherical to slightly compressed, up to 70×60 μm in diameter, with stellate projections. *M. amphibiorum* is distinguished by poor ramification of the sporangiophores and by globose sporangiospores. Ethanol and nitrates are not assimilated (Schipper 1978a; Scholer et al. 1983; de Hoog et al. 2000).

MUCOR CIRCINELLOIDES VAR. TIEGH

M. circinelloides is a common and variable species that includes four forms: *circinelloides*, *lusitanicus*, *griseocyanus*, and *janssenii* (Schipper 1978a; Scholer et al. 1983). It has been reported as a rare cause of cutaneous infections in humans (Fetchick et al. 1986; Berenguer et al. 1988; Wang et al. 1990; Fingeroth et al. 1994; Chandra and Woodgyer 2002) and from mycoses in cattle and swine (Morquer et al. 1965), birds (Porges et al. 1935; Marjankova et al. 1978), and a platypus (Stewart et al. 1999). Colonies are floccose, pale grayish-brown, and grow poorly at 37°C (maximum growth temperature 36–40°C). Sporangiophores are hyaline and mostly sympodially branched with long branches erect and shorter branches becoming circinate (recurved). Sporangia are spherical, varying from 20 to 80 μm in diameter, with small sporangia often having a persistent sporangial wall. Columellae are spherical to ellipsoidal and are up to 50 μm in diameter. Sporangiospores are hyaline, smooth walled, ellipsoidal, and 4.5–7×3.5–5 μm in size. Chlamydoconidia are generally absent. Zygospores are only produced in crosses of compatible mating types and are reddish-brown to dark brown, spherical with stellate spines, up to 100 μm in diameter and have equal to slightly unequal suspensor cells. *M. circinelloides* differs from other species of *Mucor* in its formation of short circinated (coiled), branched sporangiophores bearing brown sporangia and its ability to assimilate ethanol and nitrates (Schipper 1976; Scholer et al. 1983; Samson et al. 1995; de Hoog et al. 2000; Schipper and Stalpers 2003).

MUCOR HIEMALIS WEHMER

This species has been reported from a few cases of human cutaneous infection (Neame and Rayner 1960; Costa et al. 1990; Prevoo et al. 1991). However, with a maximum growth temperature of 30°C its pathogenicity is questionable. It is most commonly recovered from soil (Schipper 1973). Colonies are grayish-ochraceous in color. Sporangiophores are hyaline, erect, mostly unbranched, with occasional sympodial branching. Sporangia are yellow to dark brown, up to 80 μm in diameter and have a diffluent membrane. Columellae are ellipsoidal, 30×38 μm in diameter. Sporangiospores are hyaline, smooth walled, ellipsoidal, sometimes flattened on one side, and 5.5–9×2.5–5.5 μm in size. Oidia may be present in the substrate hyphae, chlamydoconidia are uncommon, and zygospores are not formed in pure culture. *M. hiemalis* is similar to *M. circinelloides* but produces larger sporangiospores, usually has unbranched sporangiophores, and is unable to grow at 37°C (Schipper 1976; Domsch et al. 1980; Samson et al. 1995; de Hoog et al. 2000; Schipper and Stalpers 2003).

MUCOR INDICUS LENDNER

M. indicus, usually referred to in the medical literature by its synonym *M. rouxii* (Calmette)Wehmer *sensu* Webmer, has been reported from human gastric (Douvin et al. 1975; Borg et al. 1990) and pulmonary (Krasinski et al. 1985) infections and from a case of necrotizing fasciitis (Mata-Essayag et al. 2001). Oliver et al. (1996) reported an interesting case of an hepatic infection in a bone marrow transplant recipient who had ingested contaminated naturopathic medicine. Colonies are characteristically deep yellow, aromatic, and have a maximum growth temperature of 42°C. Sporangiophores are hyaline to yellowish, erect or, rarely, circinate, and repeatedly sympodially branched, with long branches. Sporangia are yellow to brown, up to 75 μm in diameter, with diffluent membranes. Columellae are subglobose to pyriform, often with truncate bases, up to 40 μm high. Sporangiospores are smooth walled, subglobose to ellipsoidal, and 4–5 μm in diameter. Chlamydoconidia are produced in abundance, especially in the light. Zygospores, when formed by crosses of compatible mating strains, are black, spherical, up to 100 μm in diameter, with stellate spines and unequal suspensor cells. *M. indicus* differs from other species of *Mucor* by its characteristic deep-yellow colony color, growth at over 40°C, assimilating ethanol, but not nitrate, and being thiamine dependent (Schipper 1978a; de Hoog et al. 2000; Schipper and Stalpers 2003).

MUCOR RACEMOSUS FR.

This species has been infrequently reported as a causative agent of animal and human zygomycosis (Scholer et al. 1983). With a maximum growth temperature of only 32°C, however, its pathogenicity is questionable. Colonies are light grayish-brown in color. Sporangiophores are hyaline, erect, and show both sympodial and monopodial branching. Sporangia are brownish, up to 80–90 μm in diameter, and the membrane is mostly diffluent but persistent in smaller sporangia. Columellae are subglobose to pyriform, often with truncated bases,

light brown with collars. Sporangiospores are hyaline to pale brown, smooth walled, subglobose to broadly ellipsoidal, 8–10 μm in diameter. Chlamydoconidia are formed abundantly, but zygospores are not produced in pure culture. *M. racemosus* differs from other species of *Mucor* by the formation of chlamydoconidia in sporangiophores, its inability to grow at 37°C, and its positive assimilation of sucrose (Schipper 1976; Samson et al. 1995; de Hoog et al. 2000).

MUCOR RAMOSISSIMUS SAMUTSEVICH

M. ramosissimus has been isolated from mucocutaneous (Vignale et al. 1964), cutaneous (Weitzman et al. 1993), and rhinocerebral (Bullock et al. 1974) infections and from a case of septic arthritis in a neonate (Sharma et al. 1994). Colonial growth is restricted; it is grayish and does not grow at 37°C (maximum temperature for growth is 36°C). Sporangiophores are hyaline, slightly roughened, tapering towards the apex, and are erect with repeated sympodial branching. Sporangia are gray to black, globose or somewhat flattened, up to 80 μm in diameter and have very persistent sporangial walls. Columellae are applanate (flattened), up to 40–50 μm in size, and are often absent in smaller sporangia. Sporangiospores are faintly brown, smooth walled, subglobose to broadly ellipsoidal, 5–8×4.5–6 μm in size. Oidia may be present in the substrate hyphae, chlamydoconidia and zygospores are absent. Assimilation of ethanol is negative and that of nitrate is positive. *M. ramosissimus* differs from other species of *Mucor* by its low, restricted growth on any medium, extremely persistent sporangial walls, columellae that are applanate or absent in smaller sporangia (often resembling *Mortierella* species), short sporangiophores that repeatedly branch sympodially as many as 12 times, and the occurrence of racket-shaped enlargements in the sporangiophores (Hesseltine and Ellis 1964; Schipper 1976; Scholer et al. 1983; de Hoog et al. 2000; Schipper and Stalpers 2003).

Rhizomucor species

The genus *Rhizomucor* is distinguished from *Mucor* by the presence of stolons and poorly developed rhizoids at the base of the sporangiophores and by the thermophilic behavior of its three species: *R. miehei*, *R. pusillus*, and *R. tauricus*. All three of these species are potential human and animal pathogens and were originally classified in the genus. *R. variabilis* as described by de Hoog et al. (2000) is not thermophilic and is probably a degenerate culture of *M. hiemalis* (Voigt et al. 1999). *R. pusillus* is cosmopolitan and both *R. miehei* and *R. pusillus* have been reported as pathogens to humans and animals, the latter to the greater extent (Cooney and Emerson 1964; Hesseltine and Ellis 1973; Schipper 1978b; Scholer et al. 1983; de Hoog et al. 2000; Schipper and Stalpers 2003).

RHIZOMUCOR MIEHEI (COONEY AND EMERSON) SCHIPPER

R. miehei (synonym: *Mucor miehei* Lindt) has been reported as a rare cause of bovine mastitis (Scholer et al. 1983) and is similar in most respects to *R. pusillus* (described in the next section). However, all strains are homothallic, forming numerous zygospores, which are reddish-brown to blackish-brown, globose to slightly compressed, up to 50 μm in diameter, with stellate warts and equal suspensor cells. Colony color is a dirty gray rather than brown, and sporangia have spiny walls, are up to 50–60 μm in diameter, with columellae rarely larger than 30 μm in diameter. Growth is stimulated by thiamine, with no assimilation of sucrose and maximum temperature of growth is 54–58°C. Key features include growth at 45°C, the formation of numerous zygospores, a dirty gray culture color and a partial growth requirement for thiamine. (For further information, see Cooney and Emerson 1964; Schipper 1978b; Scholer et al. 1983; de Hoog et al. 2000.)

RHIZOMUCOR PUSILLUS (LINDT) SCHIPPER

R. pusillus (synonym: *Mucor pusillus* Lindt) is a rare human pathogen. It has been reported from cases of pulmonary (Nicod et al. 1952; Zagoria et al. 1985; Latif et al. 1997; Bjorkholm et al. 2001; Ma et al. 2001), disseminated (Meyer et al. 1973; Kramer et al. 1977; Severo et al. 1991; Gonzalez et al. 1997), and cutaneous types of infection (Wickline et al. 1989). Erdos et al. (1972) have documented a case of endocarditis and St-Germain et al. (1993) reported three cases of pulmonary and one of disseminated infection in patients with leukemia. It is more often associated with animal disease, especially bovine abortion (Smith 1989). *R. pusillus* has a worldwide distribution and is commonly associated with compost heaps. This thermophilic zygomycete is readily recognizable by its characteristic compact, low growing (2–3 mm high), gray to grayish-brown colored mycelium, and by the development of typical, sympodially branched, hyaline to yellow–brown sporangiophores (8–15 μm in diameter), always with a septum below the sporangium. Sporangia are brown or gray, globose (40–60 μm in diameter), each possessing an oval or pear-shaped columella (20–30 μm), often with a collarette (Figure 6). Sporangiospores are hyaline, smooth walled, globose to subglobose, occasionally oval (3–5 μm), and are often mixed with crystalline remnants of the sporangial wall. Chlamydoconidia are absent. Zygospores are rough walled, reddish-brown to black, 45–65 μm in diameter, and may be produced throughout the aerial hyphae in matings between compatible isolates. Temperature growth range is: minimum 20–27°C; optimum 35–55°C; maximum 55–60°C. There is positive assimilation of sucrose and no thiamine

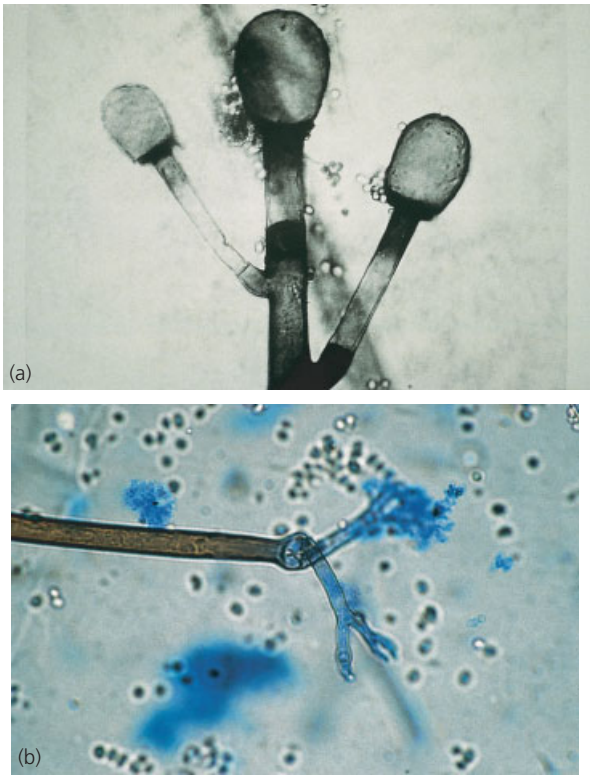

Figure 6 Rhizomucor pusillus: **(a)** *branched sporangiophores and columellae;* **(b)** *primitive rhizoids. Magnification:* **(a)** *×330 and* **(b)** *×495*

dependence. Key features include growth at 45°C, poorly developed stolons and rhizoids, branching sporangiophores with a septum below the sporangium, dark-colored sporangia without apophyses, and smooth-walled globose to subglobose sporangiospores. (For additional information, see Cooney and Emerson 1964; Schipper 1978b; Domsch et al. 1980; Ellis and Keane 1981; McGinnis 1980; Scholer et al. 1983; de Hoog et al. 2000; Schipper and Stalplers 2003.)

Rhizopus species

The genus *Rhizopus* is characterized by the presence of stolons and darkly pigmented (pheoid) rhizoids, the formation of sporangiophores singly or in groups from nodes directly above the rhizoids, and apophysate, columellate, multispored, generally globose sporangia. After spore release, the apophyses and columella often collapse to form an umbrella-like structure. Sporangiospores are globose to ovoid, one celled, hyaline to brown, and striate in many species. Colonies are fast growing and cover an agar surface with a dense cottony growth which is at first white, becoming gray or yellowish-brown with sporulation. Species of *Rhizopus* are often associated with soil, plant material, fruit, and similar substrates. Many species grow well at high temperatures, some are used in food fermentations, whereas others are pathogenic to humans and animals. (For descriptions of species, keys to taxa, and additional information, see Domsch et al. 1980; McGinnis 1980; Onions et al. 1981; Scholer et al. 1983; Schipper 1984; Schipper and Stalpers 1984, 2003; Ellis 1985, 1986; Rippon 1988; Kwon-Chung and Bennett 1992; Samson et al. 1995; de Hoog et al. 2000.)

In the past, numerous attempts have been made to clarify the species concepts of the genus *Rhizopus* (Inui et al. 1965; Zycha et al. 1969; Hesseltine and Ellis 1973). Three excellent revisions with easy-to-use keys have been produced by Schipper (1984), Ellis (1985, 1986), and Schipper and Stalpers (2003). Basically, three groups have been recognized: the 'stolonifer' group, the 'oryzae' group, and the 'microsporus' group. The GC values of the three groups have been defined by Frye and Reinhardt (1993), and temperature growth studies at 30, 36, and 45°C are characteristic for each of the groups.

The 'stolonifer' group has sporangia up to 275 μm in diameter and grows at 30°C, but has a maximum growth temperature of 36°C. Species in this group include *Rhizopus sexualis* and *Rhizopus stolonifer*. The latter has been unconvincingly implicated in human infection (Ferry and Abedi 1983), although with a maximum growth temperature of only 32°C its pathogenicity is thus questionable.

The 'oryzae' group has been reduced to a single species that is able to grow at 40°C but not at 45°C, and has sporangia not exceeding 240 μm in diameter. There is no doubt that *R. oryzae* and *Rhizopus arrhizus* are synonymous, the contentious issue being which species name to use (Schipper 1984; Ellis 1985; Frye and Reinhardt 1993). Briefly, *R. arrhizus* was described before *R. oryzae* and some authors would therefore give that name priority (Ellis 1985, 1986; Rippon 1988; Goodman and Rinaldi 1991). However, other authors consider the original identity of *R. arrhizus* as somewhat doubtful and at best an extreme or atypical form of *R. oryzae*, because it shows applanate columellae that are very unusual in *R. oryzae* (Domsch et al. 1980; Scholer et al. 1983; Schipper 1984; Kwon-Chung and Bennett 1992). The taxonomic treatment of Schipper (Schipper 1984; Schipper and Stalpers 2003) is used in this chapter; however, the synonym *R. arrhizus* is commonly used in the medical literature. *R. oryzae* is an important human pathogen.

The 'microsporus' group has simple rhizoids, and smaller sporangia up to 100 μm in diameter and grows at both 40 and 45°C. This group contains four species: *Rhizopus homothallicus*, *Rhizopus azygosporus*, *Rhizopus schipperae*, and *Rhizopus microsporus*, with the latter subdivided into three varieties, namely *R. microsporus* var. *microsporus*, *R. microsporus* var. *oligosporus*, and *R. microsporus* var. *rhizopodiformis* (Table 3). All are thermophilic and *R. microsporus* is a well-recognized pathogen of humans and animals.

Table 3 *Differentiation of pathogenic* Rhizopus microsporus *isolates*

Species	Growth at 45°C	Growth at 50°C	Main species characteristics
R. azygosporus	Good	No	Abundant azygospores
R. microsporus var. *microsporus*	Good	No	Sporangiospores angular to ellipsoidal and distinctly striate, up to 5–6 μm diameter
R. microsporus var. *oligosporus*	Restricted	No	Sporangiospores globose, up to 9 μm diameter or more, heterogeneous
R. microsporus var. *rhizopodiformis*	Good	Good	Sporangiospores globose rarely over 5 μm in diameter minutely spinulose
R. schipperae	Good	No	Abundant chlamydoconidia and restricted sporulation

RHIZOPUS AZYGOSPORUS YUAN & JONG

R. azygosporus is closely related to *R. microsporus* (Yuan and Jong 1984) and has been reported as the causative agent of three fatal cases of gastrointestinal infection in premature babies (Woodward et al. 1992; Schipper et al. 1996). Previously, this fungus was only known from its type culture, which has been isolated from tempeh, a solid fermented soybean food from Indonesia (Yuan and Jong 1984). Colonies are whitish to gray–black, producing pale brown simple rhizoids. Sporangiophores are brownish, up to 350 μm high, and 6–14 μm wide. Sporangia are grayish-black, spherical, and 50–100 μm in diameter. Columellae are subglobose to globose. Sporangiospores are ovoid to ellipsoidal, 4–5 to 6–7 μm in diameter with faint striations. Azygospores are pale to dark brown, spherical to subglobose, 30–70 μm in diameter, with coarse conical projections. All strains produce abundant azygospores in unmated isolates as a species characteristic. There is good growth at 45°C with a maximum of 46–48°C. (For further information, see Yuan and Jong 1984; Schipper et al. 1996; de Hoog et al. 2000.)

RHIZOPUS MICROSPORUS VAR. *MICROSPORUS*

R. microsporus var. *microsporus* is a rare cause of human infection (Kerr et al. 1988; Kwon-Chung and Bennett 1992). An unusual case of cellulitis in the leg of a diabetic patient was reported by West et al. (1995) and a cutaneous case in a patient with idiopathic thrombopenic purpura was reported by Kobayashi et al. (2001). Colonies are pale brownish-gray producing simple rhizoids. Sporangiophores are brownish, up to 400 μm high and 10 μm wide, but most are smaller and are produced in pairs. Sporangia are grayish-black, spherical, up to 80 μm in diameter. Columellae are subglobose to globose to conical. Sporangiospores are angular to broadly ellipsoidal to lemon-shaped, quite equal in size, up to 5–6 μm in diameter and are distinctly striate. Zygospores, formed by crosses of compatible mating strains, are dark red–brown, spherical, up to 100 μm in diameter, with stellate projections and unequal suspensor cells. There is good growth at 45°C, with a maximum of 46–48°C. (For further information, see Scholer et al. 1983; Schipper and Stalpers 1984, 2003.)

RHIZOPUS MICROSPORUS V. TIEGH. VAR. *OLIGOSPORUS* (SAITO) SCHIPPER AND STALPERS

R. microsporus var. *oligosporus* is a rare cause of human zygomycosis (Tintelnot and Nitsche 1989). Colonies are pale yellowish-brown to gray and sporulation is often poor. Rhizoids are subhyaline and simple. Sporangiophores are brownish, up to 300 μm high, and 15 μm wide, with one to three produced together. Sporangia are black, spherical, up to 100 μm in diameter. Columellae are subglobose to somewhat conical. Sporangiospores are subglobose to globose, up to 9 μm in diameter, almost smooth, with larger spores often irregular in shape (Figure 7). Chlamydoconidia are abundant, hyaline, single or in chains, spherical, ellipsoidal, or cylindrical, 7–35 μm in diameter. Zygospores are not known. There is growth at 45°C with a maximum of 46–48°C. (For further information, see Scholer et al. 1983; Schipper and Stalpers 1984; de Hoog and Guarro 1995; Samson et al. 1995.)

RHIZOPUS MICROSPORUS V. TIEGH VAR. *RHIZOPODIFORMIS* (COHN) SCHIPPER AND STALPERS

R. microsporus var. *rhizopodiformis* is the second most frequently isolated zygomycete, accounting for between 10 and 15 percent of reported human cases (Scholer et al. 1983; Kwon-Chung and Bennett 1992). It is most commonly isolated from cutaneous infections with several reports citing the use of contaminated Elastoplast bandages or wooden tongue depressors as the environmental source of the fungus (Baker et al. 1962; Ellis 1978; Gartenberg et al. 1978; Bottone et al. 1979; Everett et al. 1979; Mead et al. 1979; Sheldon and Johnson 1979; Myskowski et al. 1983; West et al. 1983; Parfrey 1986; Norden et al. 1991; Paparello et al. 1992; Mitchell et al. 1996; Verweij et al. 1997; Holzel et al. 1998). Gastrointestinal infections are also commonly reported (Neame and Rayner 1960; Waller et al. 1993; Kimura et al. 1995), but disseminated and rhinocerebral forms of infection are rare (Rosenberger et al. 1983;

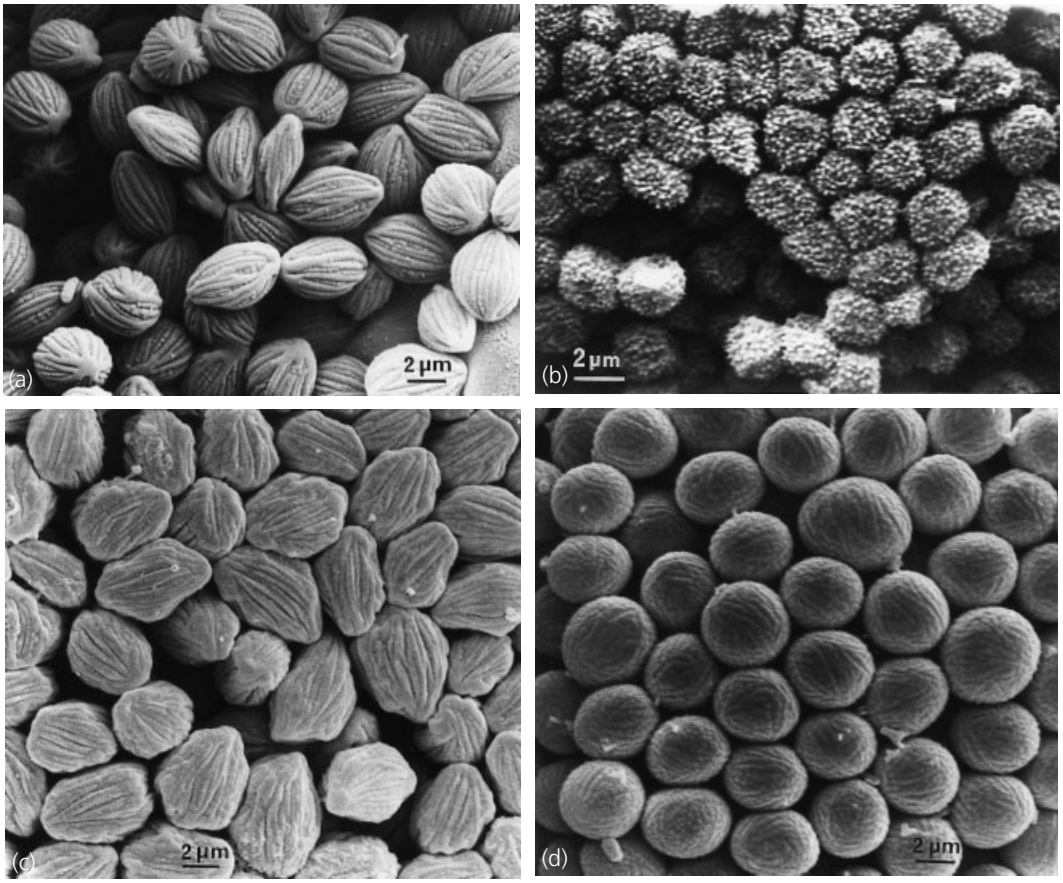

Figure 7 Rhizopus *spp.: sporangiospore ornamentation by scanning electron microscopy.* **(a)** R. microsporus *var.* microsporus*;* **(b)** R. microsporus *var.* rhizopodiformis*;* **(c)** R. oryzae *(*R. arrhizus*).* **(d)** R. microsporus *var.* oligosporus

Rangel-Guerra et al. 1985; Iqbal and Scheer 1986; Levy et al. 1986). *R. microsporus* var. *rhizopodiformis* is also an important pathogen in animals, especially in swine and bovine abortion (Dion and Sandford 1985; Smith 1989). Colonies are dark grayish-brown, up to 10 mm high with simple rhizoids. Sporangiophores are brownish, up to 500 µm high and 8 µm wide, with one to four produced together. Sporangia are bluish to grayish-black, spherical and up to 100 µm in diameter. Columellae are pyriform, comprising 80 percent of the sporangium. Sporangiospores are subglobose to globose, quite equal in size, up to 6 µm in diameter, and minutely spinulose (Figure 7). Zygospores, when formed by crosses of compatible mating strains, are reddish-brown, spherical, up to 100 µm in diameter, with stellate projections and unequal suspensor cells. There is good growth at 45°C with a maximum of 50–52°C (Bottone et al. 1979; Scholer et al. 1983; Schipper and Stalpers 1984, 2003; Ellis 1986; Polonelli et al. 1988; Waller et al. 1993; de Hoog et al. 2000).

RHIZOPUS ORYZAE WENT & PRINSEN GEERLIGS

R. oryzae (synonym: *R. arrhizus*) is the most common causative agent of zygomycosis, accounting for some 60 percent of the reported culture positive cases, and nearly 90 percent of the rhinocerebral form of infection (Scholer et al. 1983; Hyatt et al. 1992; Kwon-Chung and Bennett 1992; Hofman et al. 1993; Attapattu 1995; Adler et al. 1998; Romano et al. 2002). Pulmonary infections (Muhm et al. 1996; Yokoi et al. 1999; Vincent et al. 2000) and primary cutaneous infections (Johnson et al. 1993; Linder et al. 1998; Song et al. 1999) have also been reported. Cerebral infections have occasionally been diagnosed in leukemia patients (McGinnis 1980) and drug addicts (Oliveri et al. 1988; Fong et al. 1990). Sanchez et al. (1994) reviewed infections in AIDS patients and Winkler et al. (1996) reported a case of gastric mucormycosis in a renal transplant patient. This species has rarely been reported from animals (Smith 1989; Perelman and Kuttin 1992). *R. oryzae* (*arrhizus*) has a worldwide distribution with a high prevalence in tropical and subtropical regions. It has been isolated from many substrates, including a wide variety of soils, decaying vegetation, foodstuffs, and animal and bird dung. *R. oryzae* is often used in the production of fermented foods and alcoholic beverages in Indonesia, China, and Japan. However, it also produces the ergot alkaloid agroclavine which is toxic to humans and animals (Domsch et al. 1980; Samson et al. 1995).

Colonies are very fast growing at 25°C, reaching 5–8 mm in height, with some tendency to collapse, white and cottony at first, becoming brownish-gray to blackish-gray depending on the amount of sporulation. Sporangiophores are up to 1 500 μm in length and 18 μm in width, smooth walled, nonseptate, simple or branched, arising from stolons opposite rhizoids usually in groups of three or more (Figure 8). Sporangia are globose, often with a flattened base, grayish-black, powdery in appearance, up to 175 μm in diameter, and with many spores. Columella and apophysis together are globose, subglobose or oval, up to 130 μm in height, and soon collapse to an umbrella-like form after spore release (Figure 8). Sporangiospores are angular, subglobose to ellipsoidal, with ridges on the surface, and up to 8 μm in length. Chlamydoconidia may be formed singly or in chains and are hyaline, smooth walled, spherical to ovoid, and 10–35 μm in diameter. Zygospores, when formed by crosses of compatible mating strains, are red to brown, spherical or laterally flattened, 60–140 μm in diameter, with flat projections and unequal suspensor cells. There is no growth at 45°C, but good growth at 40°C. Key features include growth at 40°C, sporangiophores often more than 1 mm in height, rhizoids with secondary branching, and sporangia between 100 and 240 μm in diameter (Domsch et al. 1980; Scholer et al. 1983; Schipper 1984; Ellis 1985; Oliveri et al. 1988; Samson et al. 1995; de Hoog et al. 2000).

RHIZOPUS SCHIPPERAE WEITZMAN, MCGOUGH, RINALDI & DELLA-LATTA

R. schipperae belongs to the *R. microsporus* complex and is closest to *R. microsporus* var. *microsporus* (Weitzman et al. 1996). It was recently isolated from the bronchial wash and lung specimens from a patient with myeloma (Weitzman et al. 1996) and from paranasal and gastrointestinal specimens from a patient suffering heatstroke (Anstead et al. 1999). Distinguishing characteristics include the production of sporangia on a limited range of media, best on Czapek Dox agar [Oxoid (CM97), Basingstoke, Hants, UK], with clusters of up to 10 sporangiophores arising from each bundle of rhizoids and the formation of abundant, large, mostly rounded chlamydoconidia on all media. Colonies on Czapek Dox agar are grayish-white producing hyaline to pale brown simple rhizoids. Sporangiophores are brownish, 100–460 μm in length, 5–15 μm wide and may be produced singly, in pairs, or in aggregates of up to 10. Sporangia are grayish-black, spherical, and are up to 80 μm in diameter. Columellae are subglobose to subglobose–conical. Sporangiospores are subglobose to ovoid, 5–6 to 6–7 μm in diameter with faint striations. Chlamydoconidia are abundant, terminal or intercalary, globose, oval to ellipsoidal, up to 20 μm in diameter. Zygospores are unknown. Growth is on potato dextrose agar at 45°C, but not at 48–50°C, with optimal development observed at 30–35°C (Weitzman et al. 1996).

RHIZOPUS STOLONIFER (EHRENB:FR) VUILL.

R. stolonifer has been implicated only once in human infection (Ferry and Abedi 1983), and with a maximum growth temperature of only 32°C its pathogenic role is questionable. Colonies are whitish with black spots of sporangia and dark sporangiophores; they produce well-developed complex rhizoids. Sporangiophores are brownish, up to 2 000 μm high and 20 μm wide, and are usually produced in groups of one to three. Sporangia are blackish, spherical, up to 275 μm in diameter.

Columellae are conical and up to 140 μm in height. Sporangiospores are angular to globose to ellipsoidal, up to 13 μm in length, and distinctly striate. Zygospores, when formed by crosses of compatible mating strains, are black, spherical, up to 200 μm in diameter, with stellate projections and unequal suspensor cells. There is no growth at 33°C, but good growth and sporulation at 15–30°C. (For additional information, see Domsch et al. 1980; Onions et al. 1981; Schipper 1984; Samson et al. 1995; de Hoog et al. 2000.)

Saksenaea vasiformis Saksena

The genus *Saksenaea* is characterized by the formation of flask-shaped sporangia with columellae and simple, darkly pigmented rhizoids. *S. vasiformis* is the only known species and appears to have a worldwide distribution in association with soil (Saksena 1953; Hodges 1962; Ajello et al. 1976). *S. vasiformis* is an emerging human pathogen (Holland 1997) that is most often associated with cutaneous or subcutaneous lesions after trauma (Oberle and Penn 1983; Ellis and Kaminski 1985; Parker et al. 1986; Pritchard et al. 1986; Padhye et al. 1988; Goldschmied-Reouven et al. 1989; Tauphaichitr et al. 1990; Mathews et al. 1993; Bearer et al. 1994; Lye et al. 1996; Chakrabarti et al. 1997; Wilson et al. 1998). It has also been associated with rhinocerebral infection (Kaufman et al. 1988), cranial infection (Ajello et al. 1976; Dean et al. 1977), osteomyelitis (Pierce et al. 1987), necrotizing cellulitis (Patino et al. 1984), and disseminated types of infection (Torrell et al. 1981; Hay et al. 1983; Solano et al. 2000). *S. vasiformis* has also been reported from a case of bovine cranial zygomycosis (Hill et al. 1992) and from cases of invasive infection in a captive killer whale and a number of dolphins (Robeck and Dalton 2002).

Laboratory identification of this fungus may be difficult or delayed because of the mold's failure to sporulate on primary isolation media or on subsequent subculture onto potato dextrose agar. Sporulation may be stimulated by the use of nutrient-deficient media, such as cornmeal–glucose–sucrose–yeast extract agar or Czapek Dox agar, or by using the agar block method described by Ellis and Ajello (1982), Ellis and Kaminski (1985), and Padhye and Ajello (1988).

Colonies are fast growing, downy, white with no reverse pigment, and are made up of broad, nonseptate hyphae typical of a zygomycetous fungus. Sporangia are typically flask shaped with a distinct spherical venter and long neck, arising singly or in pairs from dichotomously branched, darkly pigmented rhizoids (Figure 9). Columellae are prominent and dome shaped. Sporangiospores are small, oblong, 1–2×3–4 μm in size, and are discharged through the neck after the dissolution of an apical mucilaginous plug. Key features include the formation of unique flask-shaped sporangia and failure to sporulate on primary isolation media. (For additional information, see Saksena 1953; Ellis and Hesseltine 1966; Chien et al. 1992; Kwon-Chung and Bennett 1992; de Hoog et al. 2000.)

Figure 9 Saksenaea vasiformis *showing a distinct flask-shaped sporangium. Magnification ×495*

Syncephalastrum racemosum

The genus *Syncephalastrum* is characterized by the formation of cylindrical merosporangia on a terminal swelling of the sporangiophore. Sporangiospores are arranged in a single row within the merosporangia. *S. racemosum* is the type species of the genus and a potential human pathogen; however, well-documented cases are lacking. Kamalam and Thambiah (1980) reported a case of cutaneous infection and Turner (1964) reported one of bovine mycotic abortion. It is often isolated from soil and dung in tropical and subtropical regions, and it can be a persistent laboratory contaminant. The sporangiophore and merosporangia of the *Syncephalastrum* spp. can also be mistaken for an *Aspergillus* sp. if the isolate is not looked at carefully.

Colonies are very fast growing, cottony to fluffy, white to light gray, becoming dark gray with the development of sporangia. Sporangiophores are erect, stolon-like, often producing adventitious rhizoids, and show sympodial branching (racemose branching) producing curved lateral branches. The main stalk and branches form terminal, globose to ovoid vesicles which bear finger-like merosporangia directly over their entire surface (Figure 10). At maturity, merosporangia are thin walled, evanescent, and contain globose to ovoid, 5–10(18) μm, smooth-walled sporangiospores (merospores). Optimum growth temperature is 20–40°C. Key features include the production of sympodially branching sporangiophores with terminal vesicles bearing merosporangia. (For additional information, see Domsch et al. 1980; McGinnis 1980; Onions et al. 1981; Samson et al. 1995; de Hoog et al. 2000.)

HOST RESPONSES

In general, members of the Mucorales cause the more severe forms of zygomycosis, *Mortierella* (Mortierellales)

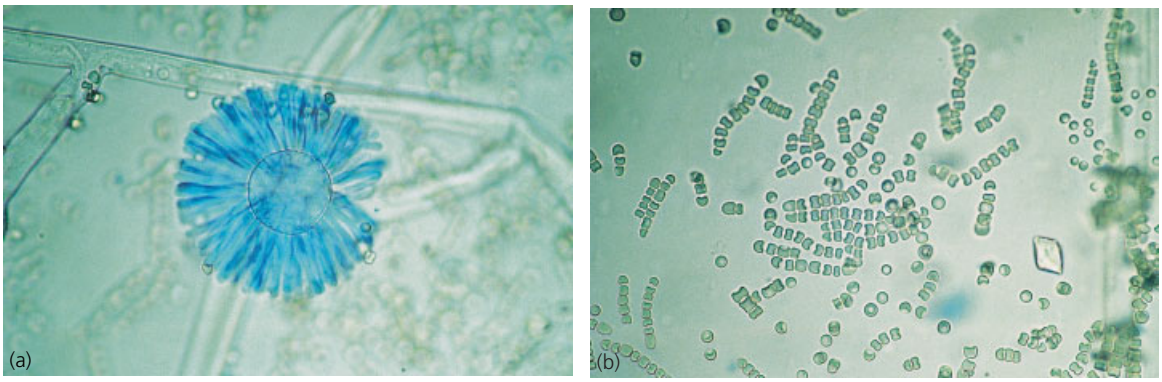

Figure 10 Syncephalastrum racemosum: **(a)** *terminal vesicle and merosporangia;* **(b)** *merospores. Magnification ×495*

is not a human pathogen, and the Entomophthorales cause more chronic disease of the nasal mucosa and subcutaneous tissue (see Subcutaneous Zygomycosis). Infections are rare in the immunocompetent patient and usually present as cutaneous lesions after the traumatic implantation of fungal elements through the skin. Lesions usually remain localized around the initial site of the inoculation and respond well to local débridement and antifungal therapy. However, zygomycosis in the debilitated patient is the most acute and fulminate fungal infection known. The disease typically involves the rhinofaciocranial area, lungs, gastrointestinal tract, skin, or, less commonly, other organ systems (Ribes et al. 2000). It is often associated with acidotic diabetes, starvation, severe burns, intravenous drug abuse, and other diseases such as leukemia and lymphoma, immunosuppressive therapy, or the use of cytotoxins and corticosteroids, therapy with desferrioxamine (an iron-chelating agent for the treatment of iron overload), and other major trauma. Infections are increasingly being reported from HIV-positive patients (Teira et al. 1993; Nagy-Agren et al. 1995; van den Saffele and Boelarert 1996). Symptoms usually develop rapidly depending on the site of infection, the immune status of the host, and degree of pathology. The infecting fungi, primarily *R. oryzae*, have a predilection for invading vessels of the arterial system, causing embolization and subsequent necrosis of surrounding tissue. A rapid diagnosis is extremely important if management and therapy are to be successful (see reviews by Rippon 1988; Goodman and Rinaldi 1991; Kwon-Chung and Bennett 1992; Ribes et al. 2000; Dromer and McGinnis 2003).

Rhinocerebral zygomycosis

Rhinocerebral infection is the most common form of the disease and is usually associated with acute, uncontrolled diabetes mellitus or acidosis (Abramson et al. 1967; Baker 1971; Rippon and Dolan 1979; Kline 1985; Reich et al. 1985; Oakley et al. 1986; Huddle et al. 1987; Ryan-Poirier et al. 1988; Bessler et al. 1994; Hopkins and Treloar 1997; Adler et al. 1998; Dokmetas et al. 2002; Romano et al. 2002). Other predisposing factors include steroid-induced hyperglycemia, especially in patients with leukemia and lymphoma, renal transplant recipients, and those receiving concomitant treatment with corticosteroids and azathioprine, and in patients with chronic alcoholism (Meyer et al. 1972; Meyer and Armstrong 1973; Hammer et al. 1975; Lyon et al. 1979; Blitzer et al. 1980; Fisher et al. 1980; Kilpatrick et al. 1983; Carbone et al. 1985; Rippon 1988; Sica et al. 1993; Nussbaum and Hall 1994; Alloway et al. 1995; Schuster and Stern 1995; Shpitzer et al. 1995; Ryan et al. 2001). Rare cases of rhinocerebral infection have also been reported in two elderly, nonketotic diabetic patients with periorbital cellulitis and blindness (O'Brien and McKelvie 1994), a patient with burns (Stern and Kagan 1999), and in an otherwise healthy patient (Radner et al. 1995). Rhinocerebral zygomycosis is usually an acute, rapidly progressive, fulminant disease, typified by local tissue necrosis progressing to sinusitis with invasion of the arterial walls, and leads to invasion of the periorbital tissue and brain. Several species have been reported as causative agents, but most human cases are caused by *R. oryzae* (Carbone et al. 1985; Rangel-Guerra et al. 1985; Parfrey 1986; Rinaldi 1989; Ribes et al. 2000). Infections usually begin in the upper turbinates or paranasal sinuses after the inhalation of sporangiospores, and may involve the orbit, palate, face, nose, or brain (Abidi et al. 1984; Morduchowicz et al. 1986; Kwon-Chung and Bennett 1992). Initial symptoms include fever, unilateral headache, nasal or sinus congestion or pain, and a serosanguineous nasal discharge. However, patients are rarely seen during early stages of infection and most present in a comatose state or with symptoms of advanced disease, such as periorbital or perinasal swelling, and a thick, bloody nasal discharge. Other symptoms include ophthalmoplegia with ptosis and proptosis, decreased visual acuity, and facial paralysis. Abnormal mental status often indicates brain involvement. If the fungus invades the palate, a black, necrotic, plaque-like lesion or fistula is often formed (Lehrer et al. 1980;

Table 4 *Agents of human zygomycosis and clinical manifestations*

Clinical manifestation	Pathogenic species reported
Rhinocerebral	*R. oryzae* (most common), *A. corymbifera*, *C. bertholletiae*, *S. vasiformis*, *A. elegans*, *M. ramosissimus*

Bigby et al. 1986; Kotzamanoglou et al. 1988; Rippon 1988; Goodman and Rinaldi 1991; Kwon-Chung and Bennett 1992; Ribes et al. 2000; Dromer and McGinnis 2003) (Table 4).

Pulmonary zygomycosis

This form of disease is progressive and usually fatal within 2–3 weeks. Infections result by inhalation of sporangiospores into the bronchioles and alveoli, leading to pulmonary infraction and necrosis with cavitation. Hematogenous dissemination to other organs, particularly the brain, often occurs (Meyer et al. 1972; Carbone et al. 1985; Rangel-Guerra et al. 1985; Bigby et al. 1986; Parfrey 1986; Rothstein and Simon 1986; Lake et al. 1988; Rippon 1988; Rinaldi 1989; Goodman and Rinaldi 1991; Kwon-Chung and Bennett 1992; Ribes et al. 2000). Predisposing conditions include: hematological malignancies, lymphoma and leukemia, or severe neutropenia, treatment with cytotoxins and corticosteroids, desferrioxamine therapy, uncontrolled diabetes, organ transplantation, and AIDS (Winston 1965; Schwartz et al. 1982; Hoffman 1987; Chavanet et al. 1990; St-Germain et al. 1993; Piliero and Deresiewicz 1995; Rickerts et al. 2000; Vincent et al. 2000). Clinical symptoms include unremitting fever and a rapidly progressive pneumonia. Hemoptysis and pleuritic chest pain may also be present. The progressive development of lung infiltrates despite broad-spectrum antibacterial treatment is a common radiological finding (Bartram et al. 1973; Skahan et al. 1991; Richardson and Warnock 1993). *R. oryzae* is the most common causative agent, followed by *A. corymbifera*, *C. bertholletiae*, and *R. pusillus* (Ventura et al. 1986; Reed et al. 1988; Rippon 1988; Ribes et al. 2000).

Gastrointestinal zygomycosis

This is a rare entity, usually associated with severe malnutrition, particularly in children, and gastrointestinal diseases which disrupt the integrity of the mucosa. Primary infections probably result after the ingestion of fungal elements and usually present as necrotic ulcers (Watson 1957; Neame and Rayner 1960; Isaacson and Levin 1961; Michalik et al. 1980; Agha et al. 1985; Carbone et al. 1985; Parfrey 1986; Gordon et al. 1988; Ismail et al. 1990; Skahan et al. 1991; Thomson et al. 1991; Mooney and Wagner 1993; Reimund and Ramos 1994; Vadeboncoeur et al. 1994; Hughes et al. 1995; Kimura et al. 1995; Singh et al. 1995; Winkler et al. 1996). Invasive gastrointestinal zygomycosis has been reported in liver transplant patients (Mazza et al. 1999; Vera et al. 2002), a renal transplant patient (Tinmouth et al. 2001), heart–lung and heart transplantation (Knoop et al. 1998), and in neonates (Amin et al. 1998; Nissen et al. 1999). An unusual case was reported from a patient with emphysematous gastritis (Cherney et al. 1999) and another in an immunocompetent host following surgery (Carr et al. 1999). Lesions are most common in the stomach, colon, and ileum (Richardson and Warnock 1993). Symptoms vary depending on the site and extent of disease.

Nonspecific abdominal pain and hematemesis are typical. Necrotic ulcers develop and peritonitis follows if intestinal perforation occurs. Intestinal infections are usually fatal within 2–3 weeks as a result of bowel infarction, sepsis, or hemorrhagic shock (Lyon et al. 1979; Rippon 1988; Rinaldi 1989; Richardson and Warnock 1993). *A. corymbifera* is probably the most frequently isolated mucoraceous causative agent, but *R. azygosporus* has been reported as the causative agent in three cases of gastrointestinal infection in premature babies (Woodward et al. 1992; Schipper et al. 1996). A rare case of colonization of gastric cancerous ulcer by *R. microsporus* var. *rhizopodiformis* has also been reported by Kimura et al. (1995).

Cutaneous zygomycosis

Clinical manifestations of cutaneous zygomycosis vary considerably depending on the status of the host and the portal of entry. Cutaneous lesions are typically single, nonspecific, and include plaques, pustules, ulcerations, deep abscesses, and ragged necrotic patches. There is often a mixed suppurative and necrotizing inflammatory reaction in the dermis and subcutaneous tissue (Goodman and Rinaldi 1991). Primary cutaneous zygomycosis is usually caused by the traumatic implantation of fungal elements through the skin, especially in

patients with extensive burns, diabetes, or steroid-induced hyperglycemia, and in cases of major trauma resulting from automobile accidents or machinery (Wilson et al. 1976; Tomford et al. 1980; Sands et al. 1985; Venezio et al. 1985; Parfrey 1986; Johnson et al. 1987; Rippon 1988; Vainrub et al. 1988; Rinaldi 1989; Tintelnot and Nitsche 1989; Skahan et al. 1991; Adam et al. 1994; Hicks et al. 1995; Liao et al. 1995; Lopes et al. 1995; Seguin et al. 1999; Song et al. 1999; Chandra and Woodgyer 2002). Cases have arisen at insulin injection sites, spider bites, entry sites of intravenous or peritoneal catheters, or operative wounds (Kwon-Chung and Bennett 1992; Baraia et al. 1995; Leong et al. 1997). In patients with burns, the initial clinical signs include fever, swelling, and changes in the appearance of the burn wound leading to severe underlying necrosis and infarction (Bruck et al. 1971; Cooter et al. 1990). Necrotizing cutaneous lesions have occurred in patients who have had contaminated surgical dressings or Elastoplast bandages applied to their skin (Gartenberg et al. 1978; Dennis et al. 1980; Patterson et al. 1986; White et al. 1986; Kerr et al. 1988; Lakshmi et al. 1993). An outbreak in neonates has been reported, caused by the use of wooden tongue depressors as splints to immobilize limbs (Mitchell et al. 1996; Tonks 1996). Cutaneous infections have also been reported from adhesive tape used to secure endotracheal tubes (Dickinson et al. 1998; Alsuwaida 2002) and from a snapdragon skin patch test (Blair et al. 2002). Reports of primary cutaneous infections in neonates appear to be increasing over time (du Plessis et al. 1997; Amin et al. 1998; Linder et al. 1998; Oh and Notrica 2002; Buchta et al. 2003). Many species have been reported as causative agents with *R. microsporus* var. *rhizopodiformis*, *R. oryzae*, and *R. pusillus* being the most common (Rippon 1988). *C. bertholletiae* has also been reported as causing a cutaneoarticular infection in an AIDS patient (Mostaza et al. 1989).

Most of the reported infections with *S. vasiformis* and *A. elegans* have been localized to the site of trauma in a previously normal host (Kwon-Chung and Bennett 1992). In the immunocompetent patient, infections usually remain localized around the site of the initial trauma and respond well to local débridement and antifungal therapy (Song et al. 1999; Kimura et al. 1999); however, in the immunosuppressed patient, infections may rapidly disseminate and require much more aggressive management. Cutaneous and subcutaneous zygomycosis may also be the result of hematogenous spread or direct invasion from other organs, and usually indicates a very poor prognosis (Goodman and Rinaldi 1991; Ribes et al. 2000).

Disseminated zygomycosis

Systemic infections may originate from any of the above, but are usually seen in neutropenic patients with pulmonary infection and less commonly from the gastrointestinal tract, burns, or other cutaneous lesions (Ingram et al. 1989; Richardson and Warnock 1993). Recent reports have also indicated an association between desferrioxamine use and disseminated zygomycosis, particularly in dialysis patients (Windus et al. 1987; Boelaert et al. 1988; Rex et al. 1988; Ryan-Poirier et al. 1988; Sane et al. 1989; Goodman and Rinaldi 1991; Prokopowicz et al. 1994). The most common site of spread is the brain, but metastatic necrotic lesions have also been found in the spleen, heart, and other organs (Tuder 1985; Iqbal and Scheer 1986; Bosken et al. 1987; Kalayjian et al. 1988; Rippon 1988; Rozich et al. 1988; Rinaldi 1989; Severo et al. 1991; Teira et al. 1993; Fortun et al. 1995; Paterson et al. 2000; Eucker et al. 2001). Infections are usually diagnosed postmortem unless there are metastatic cutaneous lesions. Cerebral infection after hematogenous dissemination results in abscess formation and infarction, and is thus distinct from the rhinocerebral form of infection (Richardson and Warnock 1993). Patients usually present with sudden onset of focal neurological deficits or coma. Traumatic implantation leading to brain abscess has been reported in intravenous drug abusers and AIDS patients (Pierce et al. 1982; Lawrence et al. 1986; Parfrey 1986; Woods and Hanna 1986; Kasantikul et al. 1987; Cuadrado et al. 1988; Oliveri et al. 1988; Smith et al. 1989; Stave et al. 1989; Fong et al. 1990; Hopkins et al. 1994). Sporadic reports of other miscellaneous types of zygomycosis include endocarditis (Virmani et al. 1982; Zhang et al. 2002), osteomyelitis (Echols et al. 1979; Pierce et al. 1987; Eaton et al. 1994; Meis et al. 1994), renal infections (Langston et al. 1973; Low et al. 1974; Levy and Bia 1995; Melnick et al. 1995; Utas et al. 1995; Gonzalez et al. 1997), and a case of fatal penile necrosis in a patient with undiagnosed diabetes (Williams et al. 1995).

LABORATORY DIAGNOSIS

As zygomycosis is such an aggressive and rapidly fatal infection, it is essential to make an early diagnosis, although at times this may be very difficult. The diagnosis is usually made by demonstrating the characteristic ribbon-like, aseptate hyphae in tissue and culture of the causative agent. Despite being recognized as common laboratory contaminants, zygomycetes are infrequently isolated in the clinical laboratory. Therefore, in patients with any of the above predisposing conditions, especially diabetes or immunosuppression and/or clinical symptoms, the isolation of any zygomycete fungus should be regarded as potentially significant. Obviously, in patients without predisposing conditions, the isolation of a zygomycete from a nonsterile site, such as skin or sputum, must be interpreted with caution, especially in the absence of direct microscopic detection in clinical specimens.

Clinical material

Clinical material may include:

- skin biopsies from cutaneous lesions
- sputum and needle biopsies from pulmonary lesions
- nasal discharges, scrapings, and aspirates from sinuses in patients with rhinocerebral lesions
- biopsy tissue from patients with gastrointestinal and/or disseminated disease.

However, as most specimens are collected from abscesses and necrotic tissue, a biopsy usually provides the best specimen; swabs are not recommended. Ideally, tissue specimens should include both normal tissue, and the center and edge of the lesion. Tissue samples should be kept moist with saline or brain–heart infusion broth and be transported to the laboratory as soon as possible. It is essential that both direct microscopy and culture be performed on all specimens. It should also be noted that zygomycetous fungi have coenocytic hyphae, which will often be damaged and become nonviable during the biopsy procedure (especially scrapings and aspirates), or by the chopping up or tissue grinding processes in the laboratory. This is why zygomycetous fungi which are clearly visible in direct microscopic or histopathological mounts are often difficult to grow in culture from clinical specimens. If on clinical and/or radiological evidence zygomycosis is suspected, excessive tissue damage when collecting the specimen should be avoided if possible and in the laboratory the tissue should be gently teased apart and inoculated directly onto the isolation media.

Direct microscopy and histopathology

Microscopy is the most rapid diagnostic method and the presence in clinical specimens of broad, 10–15 μm wide, infrequently septate, thin-walled hyphae, which often show focal bulbous dilatations and irregular branching, is diagnostic for zygomycosis (Figure 11). Scrapings, sputum, and exudates may be examined using 10–20 percent KOH and Parker ink or Calcofluor mounts. The demonstration of zygomycetous hyphae on direct microscopy from such nonsterile sites is essential in order to determine the significance of a positive culture. Tissue sections should be stained with hematoxylin and eosin (H&E), Gomori's methenamine silver (GMS) (Grocott 1955), and periodic acid–Schiff (PAS) stains. Staining reactions may be variable; however, unlike *Aspergillus* spp. mycelium, zygomycete hyphae are usually clearly visible in H&E-stained sections. Nevertheless, a GMS stain should always be performed (Chandler et al. 1980; Rippon 1988). Apart from the presence of the characteristic ribbon-like hyphae, the main histopathological features of zygomycosis are necrosis with acute and chronic infiltrates and involvement of blood vessels. Blood vessel invasion is quite frequent, resulting in thrombi, infarction, and necrosis of blood vessels. Occasionally, sporangia with well-delineated columellae and sporangiospores may be seen in tissue sections of nasal and pulmonary tissue that are well aerated (Chandler et al. 1980; Salfelder 1990; Ribes et al. 2000).

Culture

Nutritionally, members of the Mucorales are not particularly fastidious and will grow on most routine fungal

culture media provided they do not contain cycloheximide (actidione). However, the use of antibacterial antibiotics such as chloramphenicol and gentamicin in primary isolation media is recommended to prevent bacterial contamination. Media containing dextrose as a carbon source and ammonium or peptone as nitrogen sources are preferred (Scholer et al. 1983). Sabouraud's dextrose agar containing antibiotics is usually used as the primary isolation medium, with potato dextrose agar frequently used for culture maintenance and identification purposes. Thiamine is the only growth factor required by some species, such as *A. corymbifera*; however, sufficient amounts are usually present in agar containing peptone (Scholer et al. 1983). Most mucoraceous species sporulate profusely and are fast growing, often pushing the lid off the petri dish in a few days. However, laboratory identification of some species, especially *A. elegans* and *S. vasiformis*, may be difficult or delayed because of their failure to sporulate on primary isolation media or on subsequent subculture onto potato dextrose agar. Sporulation may be stimulated by the use of nutrient deficient media, such as cornmeal–glucose–sucrose–yeast extract agar, Czapek Dox agar, or by using the agar block method described by Ellis and Ajello (1982) and Ellis and Kaminski (1985).

Immunology and serology

Several studies have investigated the ability of members of the Mucorales to cause infection in normal, cortisone-treated and alloxan-induced diabetic animals (Waldorf and Diamond 1989). Diabetic animals develop a rapidly fatal infection when challenged with *R. oryzae*, *R. pusillus*, *R. microsporus* var. *oligosporus*, and *A. corymbifera* (Reinhardt et al. 1981). Intranasal or itrasinus inoculation of *R. oryzae* into streptozotocin-induced diabetic mice results in typical pulmonary or rhinocerebral infections (Waldorf et al. 1984b). Unlike other models of zygomycosis (Waldorf et al. 1982), these diabetic models lead to induction of specific enhanced susceptibility to infection by *Rhizopus* spp., resembling the predisposition to zygomycosis which occurs in uncontrolled human diabetic patients (Waldorf and Diamond 1989). *Rhizopus* spp. spore germination occurs in tissues of diabetic or cortisone-treated mice after intranasal inoculation, but not in normal animals (Lundborg and Holma 1972; Smith 1976; Waldorf et al. 1982, 1984a; Waldorf and Diamond 1984). Thus, prevention of zygomycosis appears to require inhibition of sporangiospore germination by the bronchoalveolar macrophage, thereby preventing conversion of the fungus to its hyphal form, although resident bronchoalveolar macrophages are unable to kill *R. oryzae* spores (Lundborg and Holma 1972). The invasive hyphal elements seen in tissue are too large to be ingested by phagocytic cells, and it would appear that neutrophils have an important role to play in killing hyphae of *R. oryzae* (Diamond and Clark 1982; Schaffner et al. 1986). Isolates of *R. oryzae* also produce an alkaline protease with proteolytic activity within the normal physiological pH range. However, further studies are needed to examine the role of enzymes and toxins in the virulence of these fungi (Waldorf and Diamond 1989). In general, however, most data suggest that pathogenicity of the zygomycetes depends primarily on the susceptibility of the host rather than on the pathogenic potential of the fungus.

The development of serological assays for the early diagnosis of zygomycosis has proved to be very difficult. Sera from proven cases are difficult to obtain because infections are infrequently diagnosed. Only weak antibody responses are detected in humans, probably related to the depressed immunological status of the patients and the rapid progressive course of infection, which often leads to death before significant production of specific antibodies. However, some laboratories have developed 'in house' immunodiffusion and ELISA tests for the detection of antibodies to zygomycetes (Jones and Kaufman 1978; Waldorf et al. 1982; Lawrence et al. 1986; Wysong and Waldorf 1987; Kaufman et al. 1989, 1990). Exoantigen tests for the rapid identification of nonsporulatng strains of *A. elegans* and *S. vasiformis* have been developed (Lombardi et al. 1989). The development of more sensitive DNA-based diagnostic methods, antigen detection, or specific serological procedures may prove to be more valuable in the future (Dromer and McGinnis 2003).

TREATMENT (MANAGEMENT/THERAPY)

The successful management of infections caused by mucoraceous zygomycetes requires an early diagnosis, control or reversal of any predisposing factors or underlying disease, antifungal therapy, and aggressive surgical débridement which may have to be repeated until all infected necrotic tissue is removed.

Amphotericin B is the drug of choice and full-dose therapy of 1.0 or 1.5 mg/kg/day is necessary. Lower dosages of 0.8–1.0 mg/kg/day and/or alternate day therapy may be considered after the patient has been stabilized with no new areas of necrosis developing (Andriole and Bodey 1994). Some patients may require a total dose of up to 4 g (Sugar 1992). Liposomal amphotericin B is increasingly being used, as it is much better tolerated than conventional amphotericin B and doses as high as 3–5 mg/kg/day may be given (Grauer et al. 1993; Munckhof et al. 1993; Berenguer et al. 1994; Lim et al. 1994; Ng and Denning 1995; Strasser et al. 1996; Saltoglu et al. 1998; Bjorkholm et al. 2001; Cagatay et al. 2001; Cloughley et al. 2002; Ma et al. 2001; Handzel et al. 2003; Kofteridis et al. 2003). Amphotericin B is generally continued for 8–10 weeks. To date other antifungal

agents such as 5-fluorocytosine, the azoles, or the echinocandins have had no role in the management of zygomycosis. However, recent in vitro data (Sun et al. 2002a, b; Dannaoui et al. 2003) and in vivo data for the new triazole agent posaconazole have demonstrated promising activity against the zygomycetes (Greenberg et al. 2003; Tobon et al. 2003). Antifungal susceptibility testing of these fungi is also not reliable and has an uncertain place in guiding therapeutic decisions.

In the diabetic patient prompt correction of acidosis is essential and with early diagnosis and treatment, 50–85 percent of patients with rhinocerebral zygomycosis can be cured (Pillsbury and Fischer 1977; Meyers et al. 1979; Lehrer et al. 1980). The best prognosis is among those without extension into the brain or the internal carotid artery. The most critical decisions all concern balancing the extent of surgery between that necessary to control progressive disease and that which causes unnecessary loss of the eye or gaping operative wounds (Kwon-Chung and Bennett 1992). By contrast, few leukemia patients with the infection recover (Richardson and Warnock 1993).

Treatment of pulmonary, gastrointestinal, or disseminated zygomycosis has been successful too rarely to judge appropriate therapy, but intravenous amphotericin B and decreased immunosuppression appear important in survival (Kwon-Chung and Bennett 1992). In normal patients with localized cutaneous lesions surgical débridement is often sufficient alone, although intravenous treatment with amphotericin B is also indicated. Adjunctive therapies using G-CSF (Sahin et al. 1996; Gonzalez et al. 1997; Leong et al. 1997; Ma et al. 2001; Slavin et al. 2002), GM-CSF (Leleu et al. 1999; Garcia-Diaz et al. 2001; Ma et al. 2001; Mileshkin et al. 2001; MacKenzie et al. 2002), interferon-gamma (Okhuysen et al. 1994), and hyperbaric oxygen have been used with increasing frequency (Ferguson et al. 1988; Okhuysen et al. 1994; Kajs-Wyllie 1995; Bentur et al. 1998; Gonzalez et al. 2002).

Clinical manifestations	6	Prevention	43
Epidemiology of aspergillosis	20	References	45
Host defense	20		

The accumulation of data on many aspects of *Aspergillus* spp. and aspergillosis justifies a text of major proportions. Many monographs, reviews, and journal supplements have more than adequately covered the organisms and the complete disease area (Raper and Thom 1965; Rinaldi 1983; Al-Doory and Wagner 1985; Walsh and Pizzo 1988; Cohen 1991; Barnes and Denning 1993; Brakhage et al. 1999; Latgé 1999). More recent overviews of aspergillosis can be found in Marr et al. (2002), Richardson and Warnock (2003), Wiederhold et al. (2003), and a supplement of *Clinical Infectious Diseases* (Advances against aspergillosis 2003). Arguably the most comprehensive resource is the *Aspergillus* website (www.aspergillus.man.ac.uk). The content of this website is updated regularly. The aim of this chapter is to present the reader with a summary of the organisms and an overview of the major clinical manifestations in order to present a contemporary account of the pathogenesis of the disease, new diagnostic procedures, and new perspectives on treatment.

BRIEF DESCRIPTION OF THE GENUS

Aspergillus is a very large genus containing over 185 species to which humans are constantly exposed. Only a small number of these species have, however, been associated with disease. Of these, over 95 percent of all infections are caused by three species: *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus niger*. Several more species have been reported in association with aspergillosis cases, including *Aspergillus nidulans*, *Aspergillus terreus*, *Aspergillus oryzae*, *Aspergillus ustus*, and *Aspergillus versicolor*.

Of the documented species of *Aspergillus*, *A. fumigatus* causes the large majority of cases of both invasive and non-invasive aspergillosis. Indeed, the allergic forms of the disease appear to be almost exclusively caused by this organism. Both aspergilloma and invasive aspergillosis are also caused by *A. flavus* and *A. niger*. More recently, cases of invasive aspergillosis caused by *A. terreus* and *A. nidulans* have been reported.

The fungi classified in the genus *Aspergillus* are anamorphic (asexual) filamentous organisms which reproduce by means of asexual spores termed conidia. Teleomorphic (sexual) forms of many aspergilli have been described. The aspergilli produce conidia in a basipetal fashion, which results in a chain of asexual conidia (the youngest conidium at the base and the oldest at the tip of the chain). The conidiogenous cell is termed a phialide. The base of the conidiophore, where it originates from the parent vegetative hypha, is termed a foot cell.

The conidiophore is hyphal-like and enlarges at its apex to form a swollen vesicle. Phialides may arise directly from the vesicle (uniseriate) or from sterile cells called metulae (biseriate); in some species, such as *A. flavus*, both conditions may exist in the same head. In the past, phialides were incorrectly referred to as sterigmata, a term that should be restricted to structures formed by Basidiomycetes.

A number of reference sources on the mycology of the aspergilli culminated in the publication in 1965 of a

manual by Raper and Thom (1965) in which the total number of known species and varieties were classified into 18 groups, 132 species, and 18 varieties. Since that time numerous new species and varieties have been described.

The identification of species of *Aspergillus* is not easy. Several excellent guides are available to aid in the identification of the common species of medically important aspergilli (Raper and Thom 1965; de Hoog et al. 2000). The genus *Aspergillus* is characterized by septate hyphae from which arise nonseptate conidiophores; although these conidiophores may be rough or smooth, hyaline or pigmented, they all terminate in a swollen vesicle. One or two rows of phialides are formed on the surface of the vesicle. Chains of round to oval, variously pigmented conidia are produced from the tips of the phialides. The shape of the vesicle and the arrangement of the phialides thereon determine the shape of the conidial head, from columnar to radiate, a key feature in speciating members of the genus. Finally, pigmentation of the conidia is the main factor determining the color of the colony. Following growth on appropriate media, observation of these macroscopic and microscopic features is usually sufficient to identify the organism.

The restricted list of pathogenic species of the genus suggests that these organisms may share some properties not found in other species which confer on them an intrinsic pathogenic advantage. One obvious feature that these human pathogens must share is the ability to grow efficiently at 37°C. The production of proteolytic enzymes is another property or virulence mechanism that has been investigated in the pathogenesis of invasive and allergic disease. The ability to produce elastase has been correlated with mouse virulence in strains of *A. fumigatus*. Likewise, isolates from cases of invasive aspergillosis in humans all showed the ability to digest elastin, regardless of the species. Finally, antigens with protease activity have been isolated from *Aspergillus* spp. and have been shown to react with sera from patients with allergic aspergillosis, aspergilloma, and invasive disease.

Most of the species of *Aspergillus* reproduce asexually and are classified with the Deuteromycetes (Fungi Imperfecti). However, some species, in addition to their asexual reproduction, have the characteristic of reproducing sexually by the formation of ascospores, which typifies Ascomycetes. However, for the purpose of classifying all fungi which reproduce asexually within one genus, similar to that for *Aspergillus* spp., and to avoid confusion by initiating new genera, most mycologists agree that the generic name *Aspergillus* should be applied to all species of these fungi, regardless of whether an ascosporic stage has been observed. It has been suggested that finding the sexual stage in a fungus merely completes its characterization but does not justify its inclusion in another genus; therefore, the names of the ascosporic species (the sexual stage) should be used as synonyms for certain *Aspergillus* spp., whenever this is applicable.

Accurate identification of any species of *Aspergillus* requires the isolation of a pure culture and its examination on a culture medium of known composition. Differences in the nature and composition of the culture media produce marked changes in growth characteristics and colony color, as well as in the dimensions and morphology of the microscopic components, which may lead to an inaccurate identification. Even though aspergilli can grow on almost every microbiological culture medium (liquid, solid, or semisolid), various authors have proposed standardized and reproducible formulae for media which in their experience have provided uniform cultures over long periods and which are of value for comparative studies. These media include Czapek Dox agar which is widely used as a routine medium for comparative studies and was used extensively by Raper and Thom (1965) and their coworkers. A medium used extensively for primary isolation from clinical specimens is malt extract agar on which most aspergilli sporulate freely.

In identifying aspergilli, it is important to keep in mind that there is variation among strains within species, as well as among species within a genus. Therefore, characteristics of the various groups of aspergilli may overlap. Within each strain, species, or group there are certain characteristics which can be identified.

There are several key features which are frequently consistent enough to be used to speciate individual isolates. As a result of the overlapping of criteria for identification of certain species, however, they may be classified within more than one group. The criteria in Table 1 are useful when identifying unknown isolates to species level.

The 18 groups of aspergilli classified by Raper and Thom (1965) are: *Aspergillus clavatus*, *Aspergillus glaucus*, *Aspergillus ornatus*, *Aspergillus cervinus*, *Aspergillus restrictus*, *A. fumigatus*, *Aspergillus ochraceus*, *A. niger*, *Aspergillus candidus*, *A. flavus*, *Aspergillus wentii*, *Aspergillus cremeus*, *Aspergillus sparsus*, *A. versicolor*, *A. nidulans*, *Aspergillus ustus*, *Aspergillus flavipes*, and *A. terreus*.

Although more than 180 species are found within the genus, three species, *A. fumigatus*, *A. flavus*, and *A. terreus*, account for most cases of invasive aspergillosis. The ability to distinguish between the various clinically relevant species has diagnostic value, as certain species are associated with higher mortality and increased virulence and vary in their resistance to antifungal therapy. A molecular method has been developed to identify *Aspergillus* at the species level using the 18S and 28S rRNA genes for primer binding sites (Henry et al. 2000). The contiguous internal transcribed spacer (ITS) regions, ITS 1-5.8S-ITS 2, from reference strains and clinical isolates of aspergilli were amplified, sequenced, and compared with non-reference strains in GenBank.

(*Continued over*)

Table 1 *Morphological criteria for the identification of* Aspergillus spp. (*Continued*)

Adapted from Raper and Thom (1965).

ITS amplicons from *Aspergillus* spp. ranged in size from 565 to 613 bp. Comparison of reference strains and GenBank sequences demonstrated that both ITS 1 and ITS 2 regions were needed for accurate identification of *Aspergillus* at the species level. Intraspecies variation among clinical isolates and reference strains was minimal. Other pathogenic molds demonstrated less than 89 percent similarity with *Aspergillus* ITS 1 and 2 sequences. A blind study of 11 clinical isolates was performed and each was correctly identified. The clinical usefulness of this rapid approach to identification has still to be determined. Further reviews of the major pathogenic species of aspergilli can be found in de Hoog et al. 2000; Brakhage and Langfelder 2002; Denning 2000; Varga and Töth 2003.

MORPHOLOGY

Description of colony appearance

Colonies of aspergilli may be black, brown, yellow, red, white, green, or other colors depending on the species and the growth conditions (Figures 1 and 2). The colony color always depends on the color of the microscopic components of the fungus, e.g. the color of the vegetative hyphae, the conidial heads, and the sexual structures if they are present. In addition to the color of the aerial parts of the fungal colonies, there may be pigmentation of the underlying medium, which may be different from the

Figure 1 A. fumigatus *(right) and* A. flavus *(left) cultures*

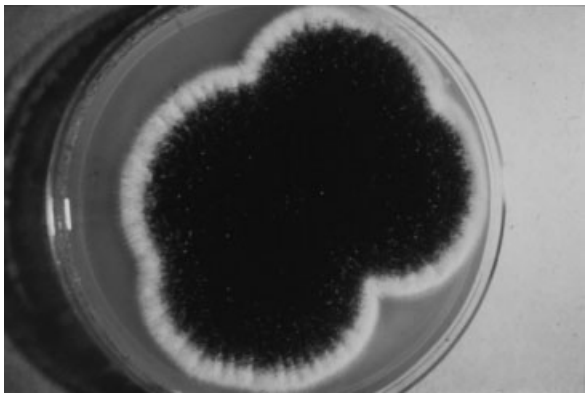

Figure 2 A. niger *culture*

color of the aerial parts of the colonies. Therefore, at any one time colonies may have one or more shades.

Even though most species of aspergilli are fast-growing fungi, there is a great deal of variation in their rate of growth. Growth rate is an important characteristic for identification of the species, so colony diameter at a certain age, under standard conditions, is a useful feature to note in the identification.

The marginal appearance of the colonies is another important characteristic. Margins may appear as heavy and sharply delineated, thin and diffuse, smooth and entire, irregularly lobed, submerged, or aerial. Also, the texture of the colonial surface may be velvety, floccose, or granular, with or without zonation. Zonation is usually expressed by alternating production of either conidial heads and sclerotia or conidial heads and cleistothecia (depending on the species).

The mycelium

The mycelium of the *Aspergillus* spp. is similar to that of most other fungi. It is well developed, with branching hyaline and septate hyphae. The hyphae may be thin or dense, and light or heavily sporulating. The cells of the hyphae are usually multinucleated. The mycelium can produce copious levels of enzymes and some produce mycotoxins. The mycelial form of *Aspergillus* spp. is characterized by vigorous growth and an abundant production of conidia carried on long, erect conidiophores. These arise from a specialized cell within the vegetative hyphae known as a 'foot cell'.

The conidial head

The conidial head of aspergilli is conventionally considered to comprise the conidia, the phialides, the vesicle, and the conidiophore, which arise from the foot cell (Figures 3, 4, 5, 6 and 7). In most species,
the shape, the size, and the color of the conidial heads within the same colony show no variation.

In the early stages of fungal growth, certain cells in the submerged or aerial parts of the vegetative mycelium enlarge and form a heavy wall. These foot cells will form a branch, which is always produced at a right angle to the hyphal cells. Not all aspergilli have distinct foot cells. The branch formed, which develops into a conidiophore, terminates in a swollen head known as a vesicle. The length of the conidiophore (between the foot cell and the vesicle) and the nature of its wall (smooth,

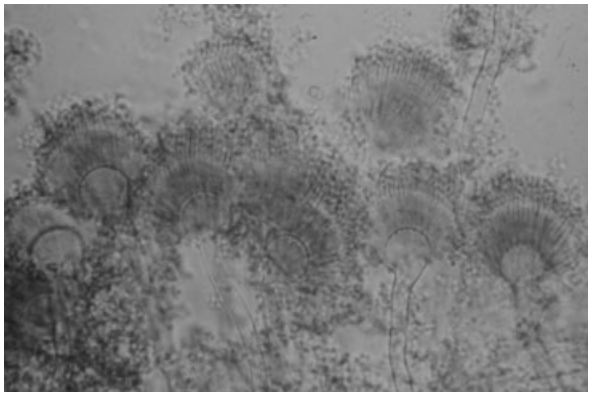

Figure 3 A. fumigatus *sporing head*

rough, echinulate, or pitted) vary from one species to another and are considered important characteristics of the species. Also, the conidiophore may be septate or nonseptate, in addition to being uniform throughout in length or greater in diameter at the base of the foot cell. Certain species, such as *A. glaucus*, may show branched conidiophores.

The vesicles vary in shape and size. They may be globose, hemispherical, elliptical, or elongated and clavate. They may have a very thin or a relatively thick wall. They are mostly hyaline, but in a few species they may appear pigmented. The lumen of the vesicle is usually a part of the conidiophore without any septum separating the vesicle from the conidiophore. These vesicles are usually borne upright on the conidiophore, with a few exceptions where they are formed at an angle to its main axis.

Depending on the species, certain areas of the vesicle surface become fertile and give rise to a layer of conidium-producing cells, which are called 'phialides'. These phialides, in some species, will cover the entire surface of the vesicle, whereas in others they may cover the upper half or three-quarters. They may vary in color in different species, from hyaline to lightly or darkly pigmented. The phialides are usually cylindrical, and are produced in different sizes and shapes, although they are usually uniform within the same culture of each species. They are produced perpendicular to the point of origin on the vesicle surface.

The cylindrical body of the phialides narrows at the apex to form a conidium-producing tube. However, depending on the species, the phialides may be formed in one layer (primary phialides), or each of these primary ones will bear one or more phialides (secondary phialides) in one linear surface. The size, shape, and length of the secondary phialides are usually different from those of primary origin. When there are secondary phialides, however, they will be the ones that narrow to form a conidium-producing tube. In some species, some of the primary phialides have been found to be septate.

Nuclear division starts within the conidium-producing structures of the phialides as a preliminary stage of conidia formation. One of the new nuclei moves upwards to the conidium-producing tube; this is followed by the formation of a septum separating the new nucleus from the rest of the cylinder. Another division follows within the cylinder and one of the newly formed nuclei moves upwards towards the tube, pushing the first nucleus (which has become a conidium by this time) out of the tube, but remaining attached to its tip. As this process continues, newly formed conidia push previously formed conidia out of the tube, thereby forming a chain of conidia at the tip of each phialide. The conidia remain attached to each other within each chain by a connective bridge, which is usually not visible with a light microscope. There are variations among the various species in the flexibility of these bridges, which affects the ease with which conidia are freed from each other.

Conidia are usually globose with a rough surface and are found in various sizes; they are mostly uninucleate. However, some have been found to contain up to 12 nuclei. The length of conidial chains, their density of packing and their orientation around the conidial heads vary from species to species and are considered part of the characteristics of the species and group. The individual color of the conidia (which may be hyaline), the collective color of the conidial mass, as well as the color of the aerial hyphae, are species characteristics that give the shade observed in the colonies.

Sexual reproduction

Many species of *Aspergillus* can reproduce sexually. Sexual reproduction in the ascosporic aspergilli is mainly by the formation of ascospores within asci. The mature ascospores are usually either in the shape of a double convex lens or two symmetrical valves, with variations among the different species. In members of the *A. nidulans* group, the color of the ascospores varies from red–brown to purple–red or violet; in the *A. ornatus* group, individual species display shades of red–brown at maturity; otherwise the ascospores are usually hyaline.

The usual number of ascospores per ascus is eight in most species.

The cleistothecium (ascocarp), where the asci are formed, varies in size, color, shape, and appearance in different species. They may appear naked or surrounded by a layer of specialized chlamydospores known as Hülle cells. These cells (which have no known function) are usually borne in hyphae as terminal or intercalary cells similar to chlamydospores. They may be globose (as in *A. nidulans*), subglobose, or elliptical in shape with very thick walls, which may occupy the whole cell body.

THE CAUSAL ORGANISMS AND THEIR HABITAT

Most human infections are caused by *A. fumigatus*, but *A. flavus*, *A. nidulans*, *A. niger*, and *A. terreus* have also been implicated. These molds are widespread in the environment. They are common soil inhabitants and are also found in large numbers in dust and decomposing organic matter. Their spores are often found in the outside air (Goodley et al. 1994; Anderson et al. 1996).

A. fumigatus is thermotolerant, able to grow over a temperature range from below 20°C up to 50°C, and grows well at over 40°C. It abounds in vegetable matter decomposing in warm environments, such as self-heating hay and composts. Strains of *A. fumigatus* can be distinguished from one another by analysis of polymorphic DNA markers (Aufauvre-Brown et al. 1992; van Belkum et al. 1993; de Hoog et al., 2000, and reviewed in Warnock et al. 2001). This approach has allowed environmental strains to be associated with particular disease entities (Symoens et al. 1993; Buffington et al. 1994; Girardin et al. 1994a, b; Tang et al. 1994; Mondon et al. 1995).

Inhalation of conidia leads to a variety of disease patterns. Atopic subjects may develop asthma. In nonatopic subjects, the presence of damaged lung tissue may result in the growth of a fungus ball (aspergilloma). Inhalation of massive doses of the conidia may lead to alveolitis. Aspergillosis also occurs in many species of birds and mammals, domesticated and wild, infected primarily by inhalation and starting as a pulmonary disease, although sometimes involving other organs. *A. fumigatus* is also one of several molds implicated in bovine mycotic abortion, probably initiated by inhalation, but with alimentary infection from spores ingested in moldy fodder as another possible route.

Nosocomial outbreaks of aspergillosis have become a well-recognized complication of construction work in or near hospital wards in which neutropenic patients are housed. In several reported outbreaks, building works adjacent to the unit in which patients were accommodated led to contamination of the air. In other outbreaks, the ventilation system for the unit drew contaminated air from neighboring building sites, or became contaminated in some other way (Goodley et al. 1994; Anderson et al. 1996; Cornet et al. 1999; Thio et al. 2000, and reviewed in Warnock et al. 2001).

The factors influencing the recovery of *Aspergillus* from the air and a comparison of the instruments available for sampling air are reviewed by Morris et al. 2000.

CLINICAL MANIFESTATIONS

Conidia of *A. fumigatus* can, because of their small size (<5 μm) and aerodynamic properties, bypass the upper respiratory tract defenses and may reach distal regions of the lung (Amitani et al. 1992, 1995). In this region the host defenses rely on phagocytic cells to remove the conidia efficiently.

An understanding of the spectrum of clinical manifestations seen in aspergillosis is also dependent on an insight into the ways in which *Aspergillus* spp. can transform from a saprophyte to a parasite. The ability of *A. fumigatus* to invade living tissue is dependent upon a number of virulence attributes (reviewed in Bouchara et al. 1995; Latgé 2001). Several reports suggest that the virulence of *A. fumigatus* is associated with the production of secreted proteases and elastases (Monod et al. 1993; Frosco et al. 1994; Moser et al. 1994; Reichard et al. 1994). Extensive colonization of lung tissue by *A. fumigatus* has suggested a key role for fungal proteases during infection. However, work by Jaton-Ogay et al. (1994) demonstrated that a serine alkaline protease (ALP) was not essential for invasion of lung tissue when ALP-negative mutants were shown to cause comparable mortality and to invade lung tissue in immunocompromised mice, as well as the parent strain (Monod et al. 1993; Tang et al. 1993). These data contrast with the work of Kolattukudy et al. (1993) who observed that an ALP-deficient mutant obtained by nitrosoguanidine treatment was less virulent than a wild-type strain of *A. fumigatus*. As proteases do not appear to play a role in the establishment of infection, other hypotheses for virulence of *A. fumigatus* have been put forward. One proposal (Jaton-Ogay et al. 1994) is that *A. fumigatus* has an ecological niche in the bronchi characterized by nutrient and temperature conditions favorable to its saprophytic growth; this results because, although this fungus accounts for only a small proportion of the airborne mold spores, it is the one isolated from lung and sputum most frequently. Consequently, invasive aspergillosis may occur when the host phagocytic defenses have been weakened by immunosuppression.

Inhalation of the conidia of *Aspergillus* spp. can give rise to a number of different clinical forms of aspergillosis, depending on the immunological status of the host (Cohen 1991; Soubani and Chandrasekar 2002; Richardson and Warnock 2003). However, there are no currently accepted classification schemes so the terminology used here may not always correspond to that adopted by other texts. Moreover, some clinical entities defy precise classification and the pathological features

at the time of diagnosis may not be known. In non-compromised individuals, *Aspergillus* spp. can act as potent allergens or cause localized infection of the lungs or sinuses.

In neutropenic patients, there is widespread growth of the fungus in the lungs and dissemination to other organs often follows. This condition is usually fatal, even if diagnosed during life and treated. It must, however, be emphasized that, with early diagnosis and treatment, a small but significant number of patients is cured.

The following sections deal, in turn, with the clinical manifestations of aspergillosis in the various organ and tissue systems, pointing out, where possible, those features that may assist in the early and definitive recognition of the disease.

Allergic aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) is characterized by recurrent pyrexia, cough, wheezing, sputum plugs containing aspergilli, and recurrent pulmonary infiltrates (Patterson et al. 1982; Ikemoto 1992; Greenberger 2002a, b, 2003; Moss 2002). This is an uncommon condition, most often seen in atopic individuals who develop bronchial allergic reactions (asthma) following inhalation of *Aspergillus* spores (Singh et al. 2003). Mucus plugs then form in the bronchi, leading to atelectasis. The illness may be mild, but it is an episodic condition and can often progress to bronchiectasis and fibrosis. ABPA is a specific disease seen in about 5 percent of asthmatic individuals; the pathology is thought to be a type III and IV reaction to inhaled conidia of *A. fumigatus*. Dual skin reactions (immediate and late) and IgG and IgE antibodies are also recognized. ABPA is thought to result from type I and III, and perhaps type IV hypersensitivity reactions to antigens released from the fungus colonizing the bronchial tree.

Against this pathological and immunological background a number of major criteria for the diagnosis of ABPA are recognized:

- asthma (reversible airway obstruction)
- eosinophilia of sputum and blood
- recurrent pulmonary infiltrates
- allergy to antigens of *Aspergillus* spp. by skin test (immediate weal–flare reaction, type I) and late reaction (Arthus, or type III).

Other criteria are:

- *Aspergillus* spp. in sputum
- raised total IgE and specific IgE and IgG in serum
- history of recurrent fever or pneumonia
- history of coughing up plugs.

The clinical course of ABPA is characterized by frequent exacerbations of cough, wheezing, and fever, with eosinophilia of sputum and blood. Allergy or infection or both may trigger the exacerbations. A significant number of patients with ABPA have clinically and immunologically demonstrable atopy. The incidence of atopy is particularly high in those patients with early-onset asthma (first decade of life).

The expectoration of sputum containing brownish mucus plugs is another feature of ABPA. Microscopy shows that the plugs are made up of eosinophils and septate hyphae embedded in mucus and fibrinous debris. Culture of the sputum may yield *A. fumigatus*. However, this is not pathognomonic, because aspergilli may occasionally be isolated from the sputum of normal people.

The most frequent symptoms seen in ABPA include fever, intractable asthma, productive cough, malaise, and weight loss. Expectoration of brown eosinophilic mucus plugs containing *Aspergillus* mycelia is common.

The radiological findings range from small, fleeting, unilateral, or bilateral infiltrates with ill-defined margins (often in the upper lobes) and hilar or paratracheal lymph node enlargement, to chronic consolidation and lobar contractions. Bronchiectasis represents the later stage of the disease. Bronchial obstruction secondary to mucus plugs often produces radiological signs and is believed to be the first step in the development of inflammation and infection that eventually lead to fibrosis. Correlation is poor between radiological and clinical findings.

The clinical features of ABPA appear to result from reaginic (IgE) and precipitating (IgG) antibodies (Brummund et al. 1987; Marchant et al. 1994). Specific IgE is believed to cause the asthma, eosinophilia, and immediate skin reaction, whereas precipitating antibodies are believed to cause the pulmonary infiltrations, damage to the bronchial wall, and late skin reaction. Serum IgE is significantly elevated in ABPA but not in other hypersensitivity lung diseases caused by, for example, inhaled organic dusts.

Reviews by Cockrill and Hales (1999), Wark et al. (2001), Chetty (2003), and Kauffman (2003) summarize the role of cellular immunity in ABPA and give very clear guidelines regarding diagnosis and treatment.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS AND CYSTIC FIBROSIS

An association between ABPA and cystic fibrosis was first reported by Mearns et al. (1965). ABPA occurs with an incidence of 10–11 percent in patients with cystic fibrosis. Nearly one-half of cystic fibrosis patients have a positive immediate weal and flare skin test to *A fumigatus* and *A. fumigatus*-specific IgE (Marchant et al. 1994) and IgG without evidence of ABPA (Knutsen et al. 1994). Aspergillus allergy appears to be coincident with *Pseudomonas aeruginosa* colonization; hence it is difficult to distinguish the effects of either organism. The diagnosis of ABPA is, however, clearly important from a clinical viewpoint because of its asso-

ciation with severe proximal bronchiectasis and a far more rapid decline in lung function in cystic fibrosis.

A greater understanding of the association between ABPA and cystic fibrosis is provided by the identification of mutations within the cystic fibrosis transmembrane conductance regulator (CFTR) gene in patients with ABPA but without clinical criteria for cystic fibrosis. Miller and colleagues analysed the entire coding region in 11 individuals who met criteria for the diagnosis of ABPA but had normal sweat electrolyte tests (Miller et al. 1996). Of the 11 patients, six had minor mutations of the CFTR gene, suggesting that CFTR plays an etiologic role in a subset of patients with ABPA. Recurrence of ABPA after lung transplant has also been described in a patient with cystic fibrosis (Fitzsimmons et al. 1997). An exhaustive review of ABPA and cystic fibrosis has been published recently (Stevens et al. 2003).

ASPERGILLUS SPP. AS FUNGAL ALLERGENS

Aspergillus spp. antigens have been studied thoroughly as allergens because *Aspergillus* conidia were among the first to be recognized as important aeroallergens (Kauffman et al. 1984).

Two antigens (18 and 20 kDa) with potential for the diagnosis of allergy have been purified from *A. fumigatus* by chromatography (reviewed in Ikemoto 1992). The 18 kDa antigen was isolated from the mycelium of ten different strains of *A. fumigatus*. Monospecific polyclonal rabbit antiserum directed against this antigen reacted with antigens of 26, 28, 44, and 46 kDa as well (Latgé et al. 1991). The characteristics of the 18 kDa antigen suggest that it is similar to Ag-2 or Ag-10 described previously from counterimmunoelectrophoresis patterns. The 20 kDa allergen is a glycoprotein that appears to be different from antigens Ag-3, Ag-5, Ag-7, and Ag-13. Another glycoprotein allergen, designated gp55, was recently isolated; its allergenic activity was sensitive to protease but not to deglycosylation. On the basis of the amino-terminal protein sequence, this appears to be a novel protein.

The amino acid sequence of the 18 kDa protein (Asp fI) has been determined partially (Burnie and Matthews 1991). Asp fI mRNA was detected in *A. fumigatus* but not in seven other *Aspergillus* spp. Asp fI shows extensive sequence homology (95 percent) to mitogillin (a cytotoxin) produced by *A. restrictus*. A cross-inhibition radioimmunoassay with a murine monoclonal antibody and human IgG and IgE antibodies revealed that Asp fI and mitogillin are indistinguishable antigenically. The simultaneous toxicity and allergenicity of Asp fI have significant implications for understanding the etiology of ABPA. Asp fI cDNA from *A. fumigatus* has now been cloned, and the recombinant allergen has been expressed and used in skin test trials. A recombinant *A. fumigatus* protein (65 kDa) expressed from a cDNA clone has also been shown to bind IgE from ABPA patients. On the basis of cDNA and deduced amino acid sequence homology to Hsp90 from other organisms, this allergen is apparently a heat-shock protein of the Hsp90 family (Burnie and Matthews 1991). The presence of non-allergenic homologs provides a significant opportunity to study the basis of allergen epitopes by focusing on the differences between these proteins, i.e. Hsp90 from *A. fumigatus* (allergenic) and Hsp90 from humans (non-allergenic). These important achievements provide a significant aid to standardizing *Aspergillus* spp. extracts and diagnosing *Aspergillus*-related diseases. However, optimal methods for the preparation of relevant antigens have still to be defined (Little et al. 1993). For detailed descriptions of those *Aspergillus* antigens approved by the allergen nomenclature committee see Banerjee and Kurup (2003) and Kurup et al. (2000).

Infection of the paranasal sinuses

Aspergillosis of the sinuses includes a number of diseases ranging from a benign non-invasive form to an aggressively invasive type. To rationalize a number of classification schemes, Talbot et al. (1991) have defined four basic types: saprophytic aspergillus colonization of a previously abnormal sinus, allergic aspergillus sinusitis, subacute or chronic invasive aspergillus sinusitis, and fulminant invasive aspergillus sinusitis. These clinical entities have in many ways pulmonary counterparts: aspergilloma, ABPA, chronic necrotizing pulmonary aspergillosis, and invasive pulmonary aspergillosis, respectively (Chang et al. 1992; De Carpentier et al. 1994; Schubert 2001; Dhiwakar et al. 2003).

Aspergillosis is currently the most common fungal infection of the paranasal sinuses (see reviews by Blitzer and Lawson 1993, Drakos 1993, and Richardson and Warnock 2003). Most patients who have developed aspergillus sinusitis have no underlying disease, although invasive rhinosinusitis has been seen in patients with acute leukemia (Talbot et al. 1991). In 20 cases of orbital aspergillosis, only one patient had diabetes. Thirty-seven patients with sino-orbital aspergillosis presented with no systemic disease. There have been only occasional reports of sinus aspergillosis arising in diabetes and leukemia patients (Peterson and Schimpff 1989). The disease runs a more fulminant course in immunocompromised patients; the mortality rate was reported as 100 percent in bone marrow transplant recipients. There is a more recent association of aspergillus sinusitis in patients with nasal allergies.

The nose and paranasal sinuses have local factors that may promote fungal infection, including nasal polyps, recurrent bacterial infections and chronic rhinitis with stagnation of nasal secretions. Some authors have suggested that occlusion of the nasal ostia of the sinuses creates an anaerobic environment that may promote fungal pathogenicity. Other reports have challenged this

concept, citing aspergillus infections in such well-aerated regions as the nose, bronchi, and external ear. Other underlying factors include prolonged antibiotic therapy for sinusitis and the greater use of antibiotics and immunosuppressive agents.

Two different forms of sinusitis due to *Aspergillus* spp. have been recognized. Acute sinusitis is a life-threatening condition encountered in immunocompromised patients. The clinical presentation is similar to that of rhinocerebral mucormycosis. The presenting symptoms include fever, nasal discharge, headache, and facial pain. Necrotic lesions develop on the hard palate or nasal turbinates and disfiguring destruction of facial tissue may occur. The infection can spread into the orbit and brain, causing thrombosis and infarction. Paranasal aspergillus granuloma formation is a slowly progressive condition. It is most common in the tropics, where *A. flavus* is the most common cause, although cases have been reported from temperate climates. Affected individuals usually complain of longstanding symptoms of nasal obstruction and headache, suggesting chronic sinusitis, but are otherwise normal. Patients present with unilateral facial pain and headache, or with facial swelling and proptosis. The swelling is firm but not usually tender. In the later stages of this condition, upward spread of the fibrosing paranasal granuloma results in focal cerebral or orbital infection. The typical radiological finding is a dense filling defect within the maxillary or ethmoid sinuses with erosion of the surrounding bone. This can be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI). A third form of aspergillus sinusitis, termed allergic fungal sinusitis (AFS), has recently been described. Up to 7 percent of patients requiring sinus surgery may have AFS.

Aspergillus sinusitis is a worldwide disease; the largest number of cases occur in hot dry climates. It may be that a hot, dry, dusty climate produces chronic nasal inflammation, allowing an ingrowth and tissue damage by the fungus and its metabolites, followed by the immunological reaction of the host to the fungal antigens. In hot, dry environments aspergillus infection has a more virulent course.

Generally, only one sinus is involved with *Aspergillus* spp., most commonly the maxillary sinus. The others, in decreasing order of frequency, are the ethmoid, sphenoid, and frontal sinuses. In a review of 103 cases (cited by Blitzer and Lawson 1993), 67 patients were found to have solitary sinus involvement (46 maxillary, eight sphenoidal, eight nasal, three ethmoidal, two frontal). Aspergillosis of the sphenoid sinus can be confusing, with reported stone formation and cavernous sinus syndrome; it can also mimic a pituitary tumor. When the disease becomes invasive, it usually spreads from the maxillary sinus to the ethmoid and then extends to the orbit and nasal cavity. Most cases of orbital aspergillosis originate in the maxillary and ethmoidal sinuses. Nasal, postnasal, sinus, and orbital symptoms are found in upper respiratory tract infections with *Aspergillus* spp. The nasal symptoms are associated with a mucoid or mucopurulent discharge, swollen nasal mucosa, enlarged turbinates, and occasional polyps or facial pain. In some cases, the secretions are gelatinous, containing necrotic tissue. Irrigation of the maxillary antrum may be difficult, and viscous or greasy material may appear in the lavage fluid. Repeated antral irrigations and antibiotics do not provide symptomatic or radiological improvement. Surgical access to the antrum reveals a thickened or polyploid antral lining, granulation tissue, and necrotic or gelatinous material, often in a cheese-like mass of brownish or greenish material. The administration of systemic corticosteroids seems to be a major factor in predisposing humans to aspergillus infection. Aspergillosis of the nose and paranasal sinuses can be classified into two types: invasive and non-invasive. In the non-invasive form, the patient complains of a nasal obstruction, rhinorrhea, and a sensation of fullness of the face. The sinus involved is opaque radiologically, without invasion. These cases appear to respond well to Caldwell–Luc procedures with an excellent prognosis. In patients with the invasive form, the disease involves the nose, orbit, palate, turbinates, and skin. Patients have pain, proptosis, and blurred vision. Radiologically, there is bone destruction, usually involving the floor of the medial orbital wall. The erosion may involve the basisphenoid and pituitary fossa, the temporal bone and pterygopalatine fossa, the alveolus with loosening of teeth, and the frontal bone. CT scanning has been very useful in defining the full extent of the disease (Ashdown et al. 1994; Krennmair et al. 1994).

Aspergillus sinusitis often produces a mixture of high- and low-density areas within the sinuses. Bone windows allow a very accurate assessment of possible invasion. MRI can be used for better definition of the high and low signals produced by the mycetoma. Despite surgical therapy, recurrences occur and multiple surgery is necessary to eradicate the disease. Direct extension or hematogenous spread from an infected sinus may cause vascular invasion. The invasive form also involves bone or meninges. In one series there were 17 deaths among 103 patients, all of which were caused by intracranial extension. Interestingly, in almost all these cases, there was no known underlying disease. Invasive sinus aspergillosis has also been reported to be associated with facial nerve paralysis, optic neuritis, arteritis, and rupture of the carotid artery. Involvement of the skull base can simulate a malignancy. Histopathologically, epithelium is ulcerated, with a dense inflammatory infiltrate of lymphocytes, plasma cells, and neutrophils. There may be bone necrosis. The granulomas have been classified as proliferative with pseudotubercles in a fibrous stroma, necrotizing with large areas of edematous necrosis, and mixed.

The diagnosis of paranasal sinusitis is nonspecific and often confusing. The differential diagnosis includes

bacterial sinusitis, malignant tumors, tuberculosis, syphilis, osteomyelitis, Wegener's granulomatosis, and rhinoscleroma. Treatment for the non-invasive form consists of sinusotomy and curettage of all diseased and necrotic tissue. This is usually curative on its own. The invasive form, however, requires radical surgical débridement and intravenous amphotericin B. Azole antifungals may have a role in treatment. Early work with itraconazole suggests that it may also have a role. Despite these measures, however, multiple recurrences requiring several procedures are the rule.

Initially, AFS was attributed to *Aspergillus* spp.; it is now clear, however, that many environmental fungi are associated with the disease (Buzina et al. 2003). *Bipolaris* spp. are the most common of this group, but *Exserohilum*, *Curvularia*, and *Alternaria* spp. have also been identified by culturing tissue. The typical patient is an immunocompetent, atopic, young adult with a longstanding history of allergic rhinitis, nasal congestion, headache, nasal polyposis, asthma, and/or recurrent sinusitis. There is a male preponderance of 2 or 3:1. The patient may have had several sinus operations over a period of years. Visual changes may have occurred, and even facial deformity has been reported as a consequence of the expansile nature of the alterations of the sinus. This form of sinusitis is initiated by hypersensitivity to fungal antigens. Immunologically, the serum IgE is increased, and the patient demonstrates a positive cutaneous skin test to the fungus. Elevated serum fungal allergen-specific IgE and IgG precipitins can be demonstrated. A non-contrast CT scan will frequently demonstrate multiple sinus involvement, with areas of high signal within the sinus. This is almost pathognomonic. Bone expansion is commonplace. Bone destruction is reported 30–50 percent of the time. At surgery, dense, inspissated, rubbery, green–brown, allergic mucoid material, and hyperplastic mucosa and polyps are noted. This mucus contains an increased number of eosinophils and Charcot–Leyden crystals, epithelial cells, and cellular debris. Areas of bone may include posterior sphenoid, ethmoid septa, laminar papyracea, and the medial antral wall. The dura, however, remains intact.

Treatment is conservative surgical drainage. Endonasal approaches to the ethmoid, sphenoid, and frontal sinuses, and the Caldwell–Luc approach to the maxillary sinuses, are reasonable choices. Systemic antifungals should be avoided unless there is definite evidence of tissue invasion or there is orbital or intracranial invasion.

The diagnosis and incidence of AFS has been revised recently by Ponikau and colleagues (1999) and Buzina et al. (2003). The objective of these studies was to re-evaluate the current criteria for diagnosing AFS and to determine its incidence in patients with chronic rhinosinusitis (CRS). This prospective study evaluated the incidence of AFS in 210 consecutive patients with CRS with or without polyposis, of whom 101 were treated surgically. A novel method of patient sampling is described where each nostril was lavaged with saline. The histopathological examination of mucin for fungi and eosinophils is emphasized. Fungal cultures of nasal secretions were positive in 202 (96 percent) of 210 consecutive CRS patients. Allergic mucin was found in 97 (96 percent) of 101 consecutive surgical cases of CRS. Allergic fungal sinusitis was diagnosed in 94 (93 percent) of 101 consecutive surgical cases with CRS, based on histopathological findings and culture results. IgE-mediated hypersensitivity to fungal allergens was not evident in the majority of AFS patients. The data from this report indicate that the diagnostic criteria for AFS are present in the majority of patients with CRS with or without polyposis. The authors propose that because the presence of eosinophils in the allergic mucin, and not a type 1 hypersensitivity, is the common feature in the pathophysiology of AFS, the clinical entity AFS should be renamed eosinophilic fungal rhinosinusitis. Molecular techniques have also been applied (Willinger et al. 2003).

Aspergilloma

This is the most familiar of the localized infections produced by *Aspergillus* spp. Typically, aspergillomas develop in old tuberculous cavities, but any cause of lung necrosis acts as a suitable environment. Fungus ball (aspergilloma) formation usually occurs in patients with residual lung cavities following tuberculosis, sarcoidosis, bronchiectasis, pneumoconiosis, and ankylosing spondylitis, or where there is a neoplasm of the lungs. Hemoptysis is the only serious complication. Fungus balls are usually located in the upper lobes. Less frequently, they occur in the apical segments of the lower lobes. Spontaneous lysis has been reported to occur in up to 10 percent of cases. Patients are often asymptomatic, but may present with chronic cough, malaise, and weight loss. Hemoptysis is the most common symptom, occurring in 50–80 percent of cases, and can, on occasion, be massive and life threatening (Jewkes et al. 1983). Chest x-rays will reveal a characteristic oval or round mass with a radiolucent halo or crescent of air over the superior aspect (Figure 8). The mass can often be shown to move as the patient changes position (Figure 9). CT will help to delineate the lesion.

Chronic pulmonary aspergillosis

A number of clinical entities have been described, including chronic necrotizing pulmonary aspergillosis (CNPA), semi-invasive aspergillosis, chronic invasive pulmonary aspergillosis, symptomatic pulmonary aspergilloma, and aspergillus pseudotuberculosis. This distinction between subacute invasive pulmonary aspergillosis, CNPA, and aspergilloma has not been rigorously defined, and an overlap in clinical and radiological features bwtween these different entities probably exists (Denning et al. 2003). In the course of their clinical practice, Denning and colleagues have observed patients

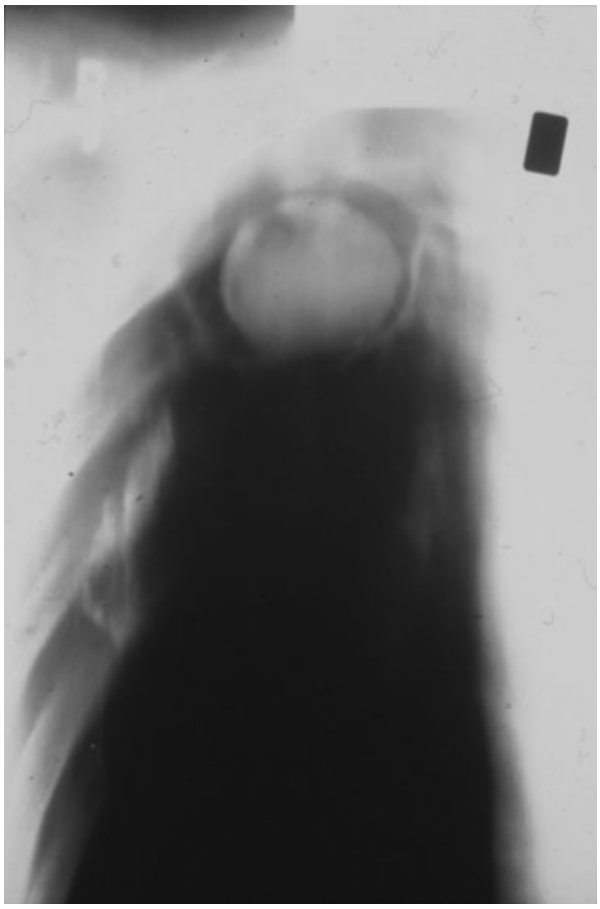

Figure 8 *Radiological appearance of an aspergilloma*

who have chronic pulmonary disease undoubtedly caused by *A. fumigatus*, with clinical features often different from that described in the older literature. Three distinct radiological patterns have been proposed. The first is characterized by the formation and expansion of multiple cavities, some containing fungus balls, which has been termed chronic cavitary pulmonary aspergillosis (CCPA). In some cases, this progresses to marked and extensive pulmonary fibrosis, which has been termed chronic fibrosing pulmonary aspergillosis (CFPA). In these patients, pleural involvement has been seen, either as direct invasion of the pleural cavity or as fibrosis. The third proposed category comprises those patients where there is progressive enlargement of a single cavity, usually with a thin wall, in some cases to substantial dimensions, occurring slowly over months or rapidly in weeks. This last group of patients appear to have slowly progressive invasive aspergillosis, a disease entity similar to or identical to the previously described CNPA. These patients appear to differ slightly from those with CCPA and CFPA because they usually have minor or moderate degrees of immune dysfunction, such as diabetes or corticosteroid use. The authors propose that this condition be called subacute invasive pulmonary aspergillosis, interchangeable with CNPA (Denning et al. 2003).

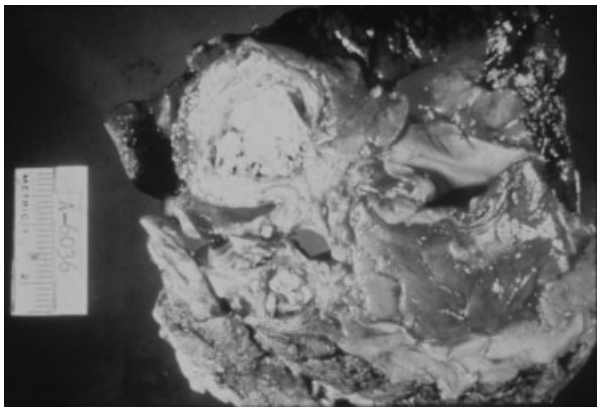

Figure 9 *Gross pathological appearance of an aspergilloma*

This condition usually occurs in middle-aged or older men with chronic or previously treated lung disease such as tuberculosis (reviewed by Binder et al. 1982). Pleural spread has been reported, but dissemination beyond the lung does not occur. The most frequent symptoms include fever, productive cough, malaise, and weight loss, often lasting for months before diagnosis. The radiological findings include a chronic progressive infiltrate representing parenchymal necrosis involving the upper lobes or the superior segment of the lower lobes. Cavitation is common and about 50 percent of patients develop single or multiple fungus balls.

Infection of the central nervous system

It is much more common for cerebral aspergillosis to occur after hematogenous dissemination of infection from the lungs than as a result of direct spread from the nasal sinuses. The brain is involved in about 10 percent of cases of disseminated aspergillosis, but cerebral infection is seldom diagnosed during life (Haran and Chandy 1993; Ashdown et al. 1994).

The symptoms of cerebral aspergillosis are gradual in onset. Confusion, behavioral alterations, and reduced consciousness in a neutropenic patient should suggest the diagnosis. Multiple brain lesions with infarction caused by cerebral arterial thrombosis often result in focal neurological signs, fits, and raised cerebrospinal fluid (CSF) pressure.

The CSF findings are normal in 50 percent of cases. In the remainder, the protein concentration may be raised, but the glucose concentration is usually normal. On occasion, a marked pleocytosis is seen. It is most unusual to recover the fungus from the CSF.

CT is often helpful in locating the lesions, but the findings are nonspecific. Meningitis is a most unusual manifestation of CNS aspergillosis.

Invasive aspergillosis

Various forms of invasive infection have increased markedly in number over the past few years (Anaissie et al.

1989; Walsh 1990; Cohen et al. 1993; Denning 1994b; Williamson et al. 1999; Dimopoulos et al. 2003; Richardson and Warnock 2003). Although the lung is the most common site of infection, aspergillosis can disseminate to virtually any body site, and indeed the true extent of this spread is often only apparent postmortem. Invasive aspergillosis is almost always seen in the setting of the immunocompromised host and is often fatal, even if diagnosed during life and treated. Those at risk include neutropenic patients with hematological malignancies, transplant recipients, and children with chronic granulomatous disease. There is widespread growth of the fungus in the lung tissue, resulting in hemorrhagic infarction. Hematogenous dissemination to other organs often follows.

The increase in the incidence of invasive aspergillosis is exemplified in a report of infections in 60 consecutive adults undergoing unrelated donor bone marrow transplantation over a 7-year period (Williamson et al. 1999). T-cell depletion was employed in 93 percent. There was a high incidence of invasive aspergillosis (17 cases), despite the use of itraconazole or amphotericin B prophylaxis. Ten of these cases occurred beyond 100 days. Two patients (11 percent) with invasive aspergillosis survived. Invasive aspergillosis was significantly associated with bacteremia and multiple viral infections.

The most common presentation in the neutropenic patient is an unremitting fever (higher than 38°C) which fails to respond to broad-spectrum antibacterial treatment. Pleuritic chest pain is not unusual. Cough may be present, but sputum production is usually minimal. Hemoptysis is uncommon.

The radiological findings are nonspecific, but the earliest lesions are single or multiple opacities. These usually progress to diffuse bilateral consolidation, or cavitation, or large wedge-shaped peripheral lesions, representing hemorrhagic infarction. These last suggest aspergillosis and their detection is sufficient justification for treatment. In 10 percent of patients with proven aspergillosis, the chest x-ray has been normal within a week of death. CT often reveals nodular lesions in patients with normal chest x-rays.

Expectoration of necrotic tissue from an infarcted lesion can leave behind what looks like a fungus ball in the lung. However, this should not be confused with the classic benign condition seen in the non-immunocompromised patient.

Hematogenous dissemination of infection from the lungs to the brain, gastrointestinal tract, and other organs occurs in up to 30 percent of patients.

The risk factors associated with invasive aspergillosis are in general similar to those for disseminated candidosis, with an even higher emphasis on prolonged neutropenia and corticosteroid treatment, particularly in combination with other immunosuppressive drugs as used in organ and bone marrow transplant recipients.

The degree and duration of granulocytopenia together are the most important predisposing host factor. The risk of developing an aspergillus infection seems to be low during the first 2 weeks of neutropenia, but after the second and third week the risk increases dramatically. Cell-mediated immunodeficiency, as in patients undergoing bone marrow transplantation or with corticosteroid therapy, is an additional risk factor.

Pulmonary CT may detect nodular lesions, sometimes with a surrounding zone of intermittent attenuation, in patients with a normal chest x-ray, and has therefore been considered extremely valuable (McWhinney et al. 1993; Gotway et al. 2002).

Specific diagnostic aspects of invasive aspergillus infections in allogenic bone marrow transplant recipients have been described also by Jantunen and colleagues (Jantunen et al. 2000). The charts of 22 consecutive patients with invasive aspergillosis transplanted in 1989–95 were reviewed. Invasive aspergillosis was diagnosed 69–466 days (median 131 days) after bone marrow transplantation. In 16 patients (73 percent), a definite or probable diagnosis of invasive aspergillosis was made during life. Respiratory symptoms were the presenting feature in half of the patients, followed by neurological symptoms (27 percent). Chest x-ray revealed single or multiple nodular lesions in ten patients; cavitation was observed in five patients. Tissue biopsy was the most common method of diagnosis (nine patients: lungs, six; liver, one; subcutaneous tissue, one; brain, one). Five cases of invasive aspergillosis were detected by nine guided fine-needle lung biopsies in eight patients and without complications. Bronchoalveolar lavage (BAL) was performed in 14 patients, with findings suggestive of invasive pulmonary aspergillosis in eight cases. Lungs were the most common organ affected (90 percent), followed by the central nervous system (CNS) (41 percent). More recent reviews and clinical surveys include those by Marr et al. (2002), Guermazi et al. (2003), and Wiederhold et al. (2003).

Acute invasive pulmonary aspergillosis

This is the most common form of invasive aspergillus infection and carries a very high mortality rate, in some studies about 95 percent (Gerson et al. 1984; Weinberger et al. 1992; Gentile et al. 1993; Ribrag et al. 1993; Richard et al. 1993; Saugier-Veber et al. 1993; Walmsley et al. 1993, and reviewed by Marr et al. 2002, Richardson and Warnock 2003, and Wiederhold et al. 2003). This type of infection may present in several forms. A bronchopneumonia with solitary or multiple infiltrates, fever, and lack of response to treatment with antibiotics is one common manifestation of acute pulmonary aspergillosis. Invasive aspergillosis of the upper airways has been described (Logan et al. 1994). Also a lobar pneumonia which resembles a bacterial infection may occur.

In the early stages of acute aspergillus bronchopneumonia, the small, patchy infiltrates may be undetectable

with ordinary chest x-rays, and in these cases CT has proved valuable for the detection of these lesions (Palmer et al. 1991; Aquino et al. 1994; Blum et al. 1994). Even in cases where the aspergillus infection presents as nonspecific infiltrates on conventional chest x-rays, a CT scan may give very valuable clues to the diagnosis by revealing a wedge-shaped, peripheral halo zone of intermediate CT attenuation surrounding a nodular infiltrate (Taccone et al. 1993). This halo is the CT correlate of hemorrhage and edema surrounding an infarct caused by thrombosis (Figure 10).

Bronchopneumonic aspergillus infiltrates later give rise to abscess formation, and not infrequently cavitary lesions may develop, often responding with neutrophil recovery (Pai et al. 1994). CT is also valuable for the demonstration of such cavitary lesions. These latter lesions may sometimes give rise to a secondary aspergilloma. Sudden life-threatening hemoptysis may supervene.

Another major manifestation of acute pulmonary aspergillosis is hemorrhagic pulmonary infarction caused by invasion and thrombosis of a large pulmonary artery. The classic clinical manifestation is sudden onset of fever, and a pleural friction rub, suggesting pulmonary thromboembolism. If uncontrolled, the aspergillus infection may extend by invasive growth into neighboring organs and structures, e.g. the mediastinum, ribs, vertebrae, esophagus, and pericardium (Ribrag et al. 1993).

The clinical manifestations described above in acute pulmonary aspergillosis are not diagnostic for this infection (Saugier-Veber et al. 1993). The diagnosis can only be made with certainty by histopathological demonstration of the fungus in a fine-needle lung biopsy, but this is not always possible in acutely ill patients, not infrequently with severe hemorrhagic diathesis. Also the tissue obtained may show only necrotic debris from infarcted areas without the characteristic aspergillus hyphae. Often, therefore, the diagnosis may only be strongly suspected by judicious interpretation of the clinical and radiological manifestations, in the presence of the most important risk factors for invasive aspergillus infection. In this setting the presence of *Aspergillus* spp. in tracheobronchial secretions should not be ignored and ascribed to contamination or colonization. It increases the likelihood of pulmonary aspergillosis.

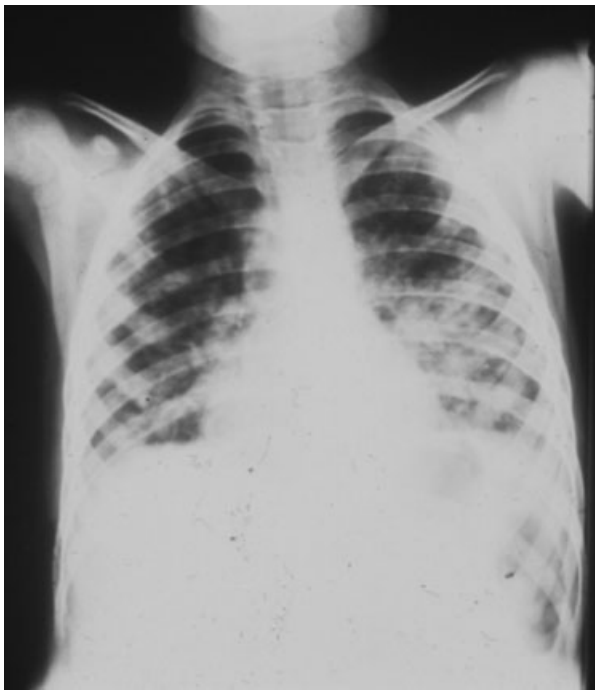

Figure 10 *Radological appearance of acute invasive aspergillosis*

Aspergillus can more readily be found in sinus washings and biopsies from necrotic lesions in the sinuses. The use of surveillance cultures is not common practice in most hospitals but may be useful. The value of antigen and antibody detection in the serological diagnosis and prognosis of invasive aspergillosis is discussed below. The value of imaging in the diagnosis of invasive aspergillosis is highlighted in reviews by Worthy et al. (1997) and Berger (1998).

Systematic CT scanning appears to allow earlier diagnosis of invasive aspergillosis. A number of studies have shown that the halo sign was highly indicative of invasive pulmonary aspergillosis in neutropenic patients. The image occurs early in the disease and predicts aspergillosis before typical cavitation. The experience of one center highlights the value of CT scanning in the early diagnosis of invasive aspergillosis. Caillot and colleagues have systemically performed CT scanning over the past 7 years in febrile neutropenic patients with pulmonary x-ray infiltrates (Caillot et al. 1997). This approach allowed the investigators to detect suggestive CT halo signs in 92 percent of 23 histologically proven and 14 highly probable invasive aspergillosis patients, compared with 13 percent before the period of analysis. The mean time to invasive pulmonary aspergillosis diagnosis was reduced dramatically from 7 ± 5.5 to 1.9 ± 1.5 days. Other centers have reported similar findings (Franquet et al. 2001).

Aspergillus fungemia

Aspergillus fungemia is encountered infrequently. In most published studies of fungemia, it is seldom mentioned. The interpretation of these data is difficult because media contamination, yielding false-positive results of cultures, often occurs. Therefore, determining the importance of aspergillus fungemia in the immunocompromised patient is particularly difficult. A review of the literature of aspergillus fungemia by Duthie and Denning (1995) suggests that both clinical and laboratory criteria have to be critically appraised before assigning the isolation of *Aspergillus* spp. from blood into one of the following: a genuine case of fungemia or, where the organism has been isolated from the blood but in an atypical clinical setting, a case not compatible

with disseminated infection (pseudofungemia). In their review of 30 cases of genuine fungemia and 34 cases of pseudofungemia, and the inclusion of two further cases of genuine infection from their own practice, a number of features emerge. A wide range of media and blood culture systems was used to isolate *Aspergillus* spp. The median time to positive blood culture was 8.5 days (range 1–27 days) in the genuine cases. Genuine aspergillus fungemia was observed more often after cardiac surgery or during neutropenia than in other settings. Other patients at risk for aspergillus fungemia were similar to those at risk for invasive aspergillosis, including patients with the acquired immunodeficiency syndrome (AIDS). Of 19 patients who were treated, seven (44 percent) survived. In the group of patients with aspergillus pseudofungemia, there were no deaths, and cultures of additional specimens from the same patient were not positive. The conclusion to be drawn from the numbers of disseminated aspergillosis is that aspergillus fungemia occurs at a far greater rate than is normally detected. Development of an optimal blood culture system may be justified for the increasing numbers of high-risk patients. Many modifications of classic blood culture systems for optimizing the isolation of fungi have been described, but very few of these have resulted in an increased isolation rate of *Aspergillus* spp. It is possible that agitation of some of the static systems may enhance the recovery of hyphal elements of this organism (Duthie and Denning 1995).

Cerebral aspergillosis

The most important organ affected in disseminated aspergillosis, apart from the lungs, is the brain (invasive aspergillosis infection), because of both its frequency and its staggering mortality. The clue to the interpretation of this clinical manifestation is the striking tendency for aspergillus hyphae to invade cerebral vessels, causing thrombosis and infarction. Accordingly, the typical manifestations of cerebral aspergillosis are focal neurological deficits including hemiparesis, focal seizures, and cranial nerve palsy. In addition, progressive signs of CNS depression may be seen. Solitary or multiple abscesses may form in an infarcted area, and a CT or MRI scan will show abnormalities consistent with infarctions or abscesses. Although the clinical and radiological manifestations of cerebral aspergillosis are not diagnostic, the presence of CNS manifestations as described in a febrile, immunocompromised patient with pulmonary infiltrates must be considered highly suggestive of disseminated aspergillosis.

Ocular infections

Three forms of ocular infection with *Aspergillus* spp. have been recognized. The traumatic implantation of the fungus into the eye may result in a corneal ulcer which can progress to perforation. Endophthalmitis is an uncommon condition, but it has been described in drug abusers, patients with endocarditis, and organ transplant recipients. It can arise following ocular trauma or hematogenous spread of the fungus. Hematogenous spread is more usual in immunocompromised patients. The symptoms include ocular pain and impaired vision.

Orbital aspergillosis can develop as an extension from infection of the paranasal sinuses. The presenting symptoms include orbital pain, proptosis, and loss of vision. In 25 percent of cases the infection spreads into the brain and causes death (Sugata et al. 1994).

Endocarditis and myocarditis

Aspergillus endocarditis tends to occur in patients undergoing open heart surgery, although it has also been described as a complication of parenteral nutrition and drug addiction. The aortic and mitral valves are the most frequent sites of infection (Motte et al. 1993). It often gives rise to large friable vegetations and large emboli are common.

The symptoms and clinical signs are similar to those of bacterial endocarditis, with prolonged fever and abnormal heart murmurs. More specific features include large friable vegetations. Emboli that obstruct major arteries, particularly those of the brain, occur in about 80 percent of cases.

Myocardial infection with abscess formation or mural vegetations may occur as a result of hematogenous dissemination. Myocarditis has been reported in about 15 percent of patients dying with disseminated aspergillosis. It can result in nonspecific ECG abnormalities or congestive heart failure.

Osteomyelitis

Aspergillus osteomyelitis is an uncommon condition, but children with chronic granulomatous disease seem to be at particular risk. In these children, spread from an adjacent lung lesion is usual, and the ribs and spine are the most common sites of aspergillus infection. In adults, the spine is also a very common site of infection, but hematogenous spread of the fungus may be more common. Paraplegia can occur.

Otomycosis

Otomycosis is the name given to growth of *Aspergillus* spp., usually *A. niger* or *A. fumigatus*, within the external auditory canal (Paulose et al. 1989). Patients present with decreased hearing, itching, pain, or discharge from the canal. Otoscopy reveals greenish or black fuzzy growth on the cerumen or debris in the auditory canal. Treatment usually consists of careful cleaning of the canal and the application of topical nystatin suspension or ointment morning and evening for 2–3 weeks. Imidazole creams such as econazole nitrate also

give excellent results. The course is chronic with acute episodes, especially in summer, and intermittent remissions. With antifungal treatment the prognosis is good.

Aspergillus spp. may invade the external auditory canal of immunocompromised patients, extending into contiguous bone or even brain.

Skin infections

Two different forms of cutaneous aspergillosis have been reported in immunocompromised patients (Carlisle 1978; McCarthy et al. 1986; Allo et al. 1987). Cutaneous lesions may arise at catheter insertion sites and as the source of a subsequent disseminated infection. The lesions begin as erythematous to violaceous, edematous, indurated plaques which evolve into necrotic ulcers covered with a black eschar.

In about 5 percent of patients with aspergillosis, hematogenous spread of infection gives rise to cutaneous lesions. These may be single or multiple, well-circumscribed, maculopapular lesions which become pustular. They evolve into ulcers with distinct borders covered by a black eschar. The lesions enlarge and may become confluent.

Primary cutaneous aspergillosis requires direct inoculation and is usually seen in immunocompromised hosts (reviewed in Groll et al. 1998b; Walsh 1998). Primary cutaneous infection has been reported at intravenous catheter sites, under occluded skin, in surgical wounds and burns, and in damaged skin, for example, venisection sites and pyoderma gangrenosum. Other cases have been reported where patients were nursed on a spinal rotorest bed designed to obviate the need for turning patients with unstable spinal injuries. The bed therefore rotates to alter sites of pressure, but the skin remains occluded with the bed sheets. Another case of primary cutaneous aspergillosis has been reported in a tetraplegic patient where there were erythematous and violaceous papules and plaques studded with pustules (Galimberti et al. 1998). It is anticipated that as the numbers of immunocompromised hosts continue to increase, the numbers of primary cutaneous aspergillosis will continue to increase in parallel with a rise in cases of invasive pulmonary aspergillosis.

Infections of the gastrointestinal tract

Gastrointestinal tract infection has been detected in 40–50 percent of patients dying with disseminated infection. The esophagus is the most frequent site of involvement, but intestinal ulcers also occur and these often result in bleeding or perforation.

Hepatic and splenic infection

This has been seen in up to 30 percent of patients with disseminated aspergillosis. The symptoms include liver tenderness, abdominal pain, and jaundice, but many patients are asymptomatic. CT scans will reveal numerous, small, radiolucent lesions scattered throughout the liver. Modest elevations in alkaline phosphatase or bilirubin concentrations can often be detected.

Aspergillosis in solid organ transplants

The incidence of invasive aspergillosis varies according to the organ transplanted, with renal transplant recipients being least at risk. Lung transplantation for cystic fibrosis carries a high risk of invasive aspergillosis (Bag 2003). In some units preoperative colonization remains a contraindication to transplantation. In early studies in lung transplant recipients, 27.5 percent developed a fungal infection postoperatively, and invasive aspergillosis accounted for 9.8 percent. Other reviews show the following pattern of incidence: liver recipients, 1–4.5 percent; kidney recipients, 0.5–2.2 percent; lung or lung–heart recipients, 18 percent (Panackal et al. 2003).

Other case series indicate that the incidence of invasive aspergillosis in liver transplant recipients appears to be 1.5–14.7 percent and the time period of highest risk post-transplant has been reported to be between 14 and 100 days. The predictors for invasive fungal infections complicating orthotopic liver transplantation (OLT) include severe renal insufficiency, prolonged operative time (>11 h), retransplantation, and colonization within 3 days of OLT. If a number of these predictors are present then the incidence of invasive fungal infection can be as high as 67 percent.

The risk factors for invasive aspergillosis in solid organ transplant recipients include: pulse steroid administration, the use of OKT3, antibiotic usage, organ failure, retransplantation, thrombocytopenia, and hospital construction. Recent data support the association between cytomegalovirus (CMV) and fungal infections in liver transplant recipients. CMV infection has been found to be present in 28.5 percent of cases of invasive aspergillosis. The use of antilymphocyte globulin, antithymocyte globulin, OKT3 monoclonal antibody, and the number of episodes of acute rejection treated are all associated with an increased risk of fungal infections.

Aspergillosis in solid organ transplant recipients present nonspecifically and their signs and symptoms often overlap with those of other infectious and non-infectious processes. In any infection diagnosed in a solid organ transplant recipient, a careful search should be made for metastatic infection, especially of the skin, the skeletal system, and the CNS. Pulmonary symptoms predominate – including nonproductive cough, pleuritic chest pain, dyspnea and low-grade fever. Chest radiology may suggest a patchy pneumonia, cavitary lung disease, or a pulmonary embolus; the chest x-ray may also be normal. From the lungs, *Aspergillus* spp. may disseminate to almost any organ, including the brain,

liver, spleen, kidney, thyroid, heart, blood vessels, bone and joints, among others. *Aspergillus* spp. may also invade the paranasal sinuses, gastrointestinal tract, or skin; rarely, it may gain entry through an intravenous catheter. *Aspergillus* spp. may cause peritonitis in renal transplant recipients on continuous ambulatory peritoneal dialysis (CAPD), or in liver transplant recipients with intra-abdominal abscesses. Endophthalmitis may occur, usually in conjunction with endocarditis. Other unusual presentations of aspergillus infections in solid organ transplant recipients include tracheobronchitis, with infection limited to the anastomotic site and large airways in heart–lung and lung transplant recipients, and wound infections.

LUNG TRANSPLANTATION

Aspergillus infections, documented in 6–8 percent of lung transplant recipients, remain among the most significant opportunistic infections after lung transplantation (Kubak 2002). Lung transplant recipients have a unique predisposition for and clinical manifestations of aspergillus infection. Direct communication of the transplanted organ with the environment, impairment in local host defenses (e.g. mucociliary clearance and cough reflex), disruption of lymphatic drainage, ischemic airway injury, altered alveolar phagocytic function, and an overall greater requirement of immunosuppression render lung transplant recipients uniquely susceptible to aspergillus airway colonization and invasive disease. Isolated tracheobronchitis and bronchial anastomotic infections are entities distinct from aspergillus pneumonia. In one study, although the early mortality of patients with bronchial anastomotic aspergillus infections did not differ significantly from patients without these infections, their long-term survival was reduced.

Aspergillus infections in lung transplant recipients have been reported largely as institutional experiences with few patients or case reports. Consequently, the risk factors, role of aspergillus airway colonization, and variables influencing outcome have not been well defined.

A recent review has identified a total of 159 cases of aspergillus infections in 40 published reports (Singh and Husain 2003). Of these, 87 were individually detailed cases, and 72 were summarized in reports containing 2–14 cases. The type of lung transplantation was reported in 66 patients. Overall, 51.5 percent (34 of 66) of the patients with aspergillus infections were single lung transplant recipients, 34.9 percent (23 of 66) were bilateral lung transplant recipients, and 13.6 percent (9 of 66) were heart–lung transplant recipients. Patients ranged in age from 19 to 64 years (median 48 years), and 64 percent were male.

The median incidence of aspergillus infection was 6.2 percent and ranged from 2.2 to 20 percent. Aspergillus infections occurred a median of 3.2 months and up to 5 years after lung transplantation. Twenty-six percent of all infections occurred within 1 month, 51 percent within 3 months, and 72 percent within 6 months of lung transplantation. Sixteen percent of the infections occurred after 6 months, and only 12 percent were documented after 12 months of transplantation.

Time of onset of infections varied significantly for different types of lung transplant recipients. The median time to onset after transplantation was 0.7 months for heart–lung, 3.9 months for bilateral lung, and 5 months for single lung transplant recipients (P=0.046). Single lung transplant recipients developed aspergillus infections significantly later after transplantation than all other patients (median 4.9 months versus 2.1 months, P=0.019). Sixty-eight percent (15 of 21) of the single lung as compared with 35 percent (9 of 26) of the bilateral lung transplant recipients developed aspergillus infection at >3 months after transplantation (P=0.021). Time of onset also differed for various types of aspergillus infections. Invasive pulmonary or disseminated aspergillosis occurred significantly later than tracheobronchitis (P=0.03). Of the aspergillus infections occurring within 3 months of transplantation, 75 percent (21 of 28) were tracheobronchitis or bronchial anastomotic infections, 18 percent (5 of 28) were invasive pulmonary infections, and 7 percent (2 of 28) were disseminated invasive infections (P=0.06). Other variables (e.g. age, chronic obstructive pulmonary disease as underlying lung disease, antilymphocyte globulin use for induction, use of antifungal prophylaxis, prior rejection or CMV infection) did not differ for patients with early- versus late-onset aspergillus infections.

Of 78 lung transplant recipients, 29 (37 percent) had tracheobronchitis, 25 (32 percent) had invasive pulmonary aspergillosis, and 16 (20 percent) had bronchial anastomotic infection. Only 10 percent (8 of 78) of the patients had disseminated invasive aspergillosis. Of these, 4 percent (3 of 78) had multiple sites of dissemination and 5 percent (5 of 78) had a single extrapulmonary site of infection documented; these included osteomyelitis in two patients (involving pelvis in one and vertebrae in the other), and thoracic wound infection, endophthalmitis, and retroperitoneal abscess in one patient each. Eight percent (3 of 36) of the patients with invasive aspergillosis were diagnosed only at autopsy.

Fifty-eight percent (19 of 33) of the single lung as compared with 45 percent (14 of 31) of all other patients had invasive aspergillosis (P=0.3). Single lung transplant recipients were older (P=0.006) and more likely to have chronic obstructive pulmonary disease as an underlying illness (P=0.05). Of the patients with invasive pulmonary aspergillosis, 67 percent (16 of 24) were single lung, 21 percent (5 of 24) bilateral lung, and 13 percent (3 of 24) heart–lung transplant recipients.

Whether invasive aspergillosis first occurred in the native or transplanted lung could be ascertained in ten patients. In nine of these, invasive aspergillosis was first documented in the native lung. The underlying lung disease in these patients was chronic obstructive

pulmonary disease in five, 1-antitrypsin deficiency in three, idiopathic pulmonary veno-occlusive disease in one, and unknown in one patient. Invasive aspergillosis occurred a median of 7 months post-transplant in these patients (range 18 days to 5 years). Seven of these 10 patients died.

In total, 91 percent of the aspergillus infections were due to *A. fumigatus*, 2 percent (1 of 40) to *A. flavus*, 2 percent (1 of 40) to *A. niger*, and 5 percent (2 of 40) were mixed infections due to two *Aspergillus* spp. Non-*A. fumigatus* spp. were associated with 10 percent (3 of 29) of tracheobronchial infection episodes, but were never associated with invasive aspergillus infections. Only 15 percent (4 of 27) of the aspergillus infections were accompanied by fever. Fever was significantly more likely to be documented in patients with invasive as compared with localized tracheobronchial aspergillus infections; 50 percent (2 of 4) of the patients with disseminated aspergillosis, 20 percent (2 of 10) of those with invasive pulmonary aspergillosis, and 0 percent (0 of 13) of those with tracheobronchial or bronchial anastomotic infections were febrile ($P = 0.046$). Prior rejection episodes were documented in 50 percent, and use of antilymphocyte preparation or OKT3 in 38 percent of the lung transplant recipients with invasive pulmonary aspergillosis. The radiographic appearance of pulmonary aspergillus infections was a focal consolidation in 40 percent (4 of 10), cavitary lesions in 30 percent (3 of 10), and nodules or mass-like lesions in 30 percent (3 of 10).

Data on aspergillus colonization could be assessed in 395 patients in 25 studies that had numerator and denominator data available. *A. fumigatus* was the most common species cultured (63 percent, 174 of 276), followed by *A. niger* (12 percent, 34 of 276), *A. versicolor* (9 percent, 26 of 276), *A. flavus* (8 percent, 21 of 276), *A. nidulans* (4 percent, 10 of 276), *A. glaucus* (3 percent, 7 of 276) and *A. terreus* (1 percent, 4 of 276). In 60.9 percent (14 of 23) of the patients, the first positive culture for *Aspergillus* was detected within 3 months of transplantation, in 4.3 percent (1 of 23) between 3 and 6 months, in 26.1 percent (6 of 23) between 6 and 12 months, and in 8.7 percent (2 of 23) at >12 months after transplantation. Of the patients with an airway culture positive for *Aspergillus*, 7.4 percent (15 of 207) had tracheobronchitis or bronchial anastomotic infection, and 20.1 percent (41 of 202) had invasive aspergillosis upon first detection of *Aspergillus*. An additional 5.7 percent (11 of 193) of the patients with a positive airway culture progressed to aspergillus infection at a later time point. These included 3.1 percent (6 of 193) with progression to tracheobronchitis, and 2.6 percent (5 of 193) with progression to invasive aspergillosis. The mortality rate was 62.5 percent (5 of 8) in those with progression due to infection and 1 percent (1 of 105) in those who remained colonized.

Overall mortality in lung transplant recipients with aspergillus infections was 52 percent (59 of 113) and varied significantly with site of infection, type of lung transplantation, time of onset of infection, and antifungal therapy employed. Mortality rate was 23.7 percent (9 of 38) for patients with tracheobronchial or bronchial anastomotic infections, 81.9 percent (18 of 22) for patients with invasive pulmonary aspergillosis, 67 percent (2 of 3) for those with disseminated invasive infection, and 33 percent (1 of 3) for patients with only an extrapulmonary site of infection (P=0.0001). Mortality for single lung transplant recipients (60 percent, 18 of 30) was significantly higher than for bilateral lung (40 percent, 6 of 15) or heart–lung transplant recipients (56 percent, 3 of 9; P=0.03). Patients with late-onset aspergillus infections had significantly higher mortality than those with early-onset infections (57 percent, 12 of 23 versus 28 percent, 7 of 25; P=0.045). However, when only the patients with invasive aspergillosis were analyzed, the mortality rate did not differ for those with late (73 percent, 8 of 11) versus early-onset aspergillus infections (71 percent, 5 of 7). Age (44.7 versus 45.5 years), rejection (76 percent, 16 of 21 versus 47.1 percent, 8 of 17), or antilymphocyte globulin use (34.6 percent, 9 of 26 versus 34.5 percent, 10 of 29) did not differ significantly in patients with aspergillus infection who lived versus those who died, respectively.

Of lung transplant recipients with invasive aspergillosis, 18 received amphotericin B, five received a liposomal formulation of amphotericin B, and one patient received amphotericin B plus itraconazole. Mortality was significantly higher in patients with invasive aspergillosis who received amphotericin B (83 percent, 15 of 18) as compared with those who received a liposomal formulation of amphotericin B or amphotericin B plus itraconazole (33 percent, 2 of 6; P=0.038). Mortality rate, however, did not differ for patients with tracheobronchitis or bronchial anastomotic infections who received amphotericin B (33 percent, 2 of 17) as compared with the other regimens (19.3 percent, 5 of 26, P >0.20). Only four patients underwent pneumonectomy for the treatment of invasive aspergillosis; all were single lung transplant recipients and three of four of these patients died. Of the four patients who underwent pneumonectomy, one each had received amphotericin B, a liposomal formulation of amphotericin B, and amphotericin B plus itraconazole as antifungal therapy; the antifungal therapy was unavailable in one patient.

Although previous reports have alluded to a higher incidence of aspergillus infections in single lung transplant recipients, the report by Singh and Husain (2003) has highlighted the unique characteristics and overall greater impact of aspergillus infections after single lung transplantation. Single lung transplant recipients were significantly older, more likely to have chronic obstructive pulmonary disease as an indication for lung transplantation, or have developed aspergillus infections later after transplantation, tended to have a higher incidence of inva-

sive aspergillosis, and had higher mortality than all other lung transplant recipients with aspergillus infections.

In the vast majority of the single lung transplant recipients, invasive aspergillosis was documented in the native lung, suggesting that the native lung may harbor a nidus for *Aspergillus* and serve as a source of infection in these patients. It is known that single lung transplant recipients are more likely to have chronic obstructive pulmonary disease, a condition which predisposes to airway colonization with *Aspergillus*. A molecular epidemiologic study in lung transplant recipients that used DNA primers for strain typing documented that, although the clinical strain of a single lung transplant recipient was identical to the one collected at home, the isolates in other lung transplant recipients were deemed to be more likely of nosocomial origin. Thus, aspergillus infections in single lung transplant recipients likely represent reactivation of a preexisting focus. The higher mortality (despite pneumonectomy) in these patients may be related to the higher incidence of invasive pulmonary as compared with tracheobronchial infections.

Characterized by endobronchial lesions ranging from erythema to ulceration and pseudomembrane formation, tracheobronchitis is an entity observed specifically in lung transplant recipients. Lesions in the vicinity of or involving the anastomotic site can result in bronchopleural fistula and fatal hemorrhage. Bronchopleural fistulas were documented in 4.4 percent (2 of 45) of the lung transplant recipients with tracheobronchial aspergillus infections. A majority of the patients in whom tracheobronchitis or bronchial anastomotic infections occurred were bilateral lung transplant recipients. Bilateral lung and right lung transplant recipients in a previous study were documented to have a higher incidence of bronchial anastomotic infection. It was proposed that bilateral lung transplant recipients may be more likely to have greater impairment of cough reflex and mucociliary clearance, leading to a higher risk of colonization and subsequent infection of the anastomotic sites. Also, bilateral lung transplant recipients undergo longer operations and may have a higher risk of ischemia in the area of anastomosis.

Two observations relevant to clinical and radiographic manifestations of aspergillus infections in lung transplant recipients deserve mention. Fever was documented in only 15 percent of the patients with aspergillus infections. Patients with invasive pulmonary or extrapulmonary aspergillosis were more likely to be febrile than those with tracheobronchitis or bronchial anastomotic infections. Second, aspergillus lung infections frequently lacked a characteristic radiographic appearance and presented most often with focal areas of patchy consolidation or infiltrate. Nodular lesions were documented in 30 percent of the patients with pulmonary aspergillosis in our study and in 27 percent in a previous report. Characteristic CT findings (e.g. halo sign) were distinctly unusual.

An optimal antifungal prophylactic strategy in lung transplant recipients has not been defined. The antifungal agent employed and the duration of prophylaxis remain controversial in these patients. Aerosolized amphotericin B and itraconazole are currently the most frequently employed antifungal prophylactic agents in lung transplant recipients. Given the variability in the route of administration, dosages, and duration of prophylaxis, the efficacy of either agent cannot be discerned incontrovertibly. However, the analysis described here allows the following conclusions that may be relevant in the approach toward antifungal prophylaxis or designing antifungal prophylactic trials. Tracheobronchial or anastomotic infections were the most frequently occurring infections within 3 months; the median time to onset was 2.7 months. Antifungal prophylaxis, if employed, may be limited to 3 months in most patients. Such a strategy utilizing an 'effective' antifungal agent could potentially prevent 62 percent of the trancheobronchial, 36 percent of the invasive pulmonary, and 50 percent of the disseminated infections. Invasive pulmonary aspergillosis, however, occurred a median of 5.5 months after transplantation. Single lung transplant recipients were significantly more likely to develop aspergillus infections after 3 months, and the native lung may have been the source in these patients. Thus, a longer duration of prophylaxis, employing a systemic antifungal agent able to achieve adequate pulmonary levels, may be preferable in these patients.

In summary, the review has highlighted an overall greater morbidity and poorer outcome in single lung transplant recipients with aspergillus infections. The single lung transplant recipients with aspergillus infections were older, more likely to have chronic obstructive pulmonary disease as an underlying illness and to have developed aspergillus infections later after transplantation, and tended to have a higher incidence of invasive aspergillosis than other lung transplant recipients. Overall mortality in lung transplant recipients with aspergillus infections was 52 percent; single lung transplant recipients and patients with late-onset aspergillus infections had significantly higher mortality. The unique epidemiologic characteristics and variables influencing outcome delineated in the review have implications relevant for the management and for designing antifungal prophylactic studies in lung transplant recipients in the future.

HEART TRANSPLANTATION

Most systemic fungal infections in heart transplant recipients are caused by *Aspergillus*, second in incidence to CMV. The infection manifestation is pneumonia occurring around 35 days post-transplantation. In one study in 844 heart transplant recipients between the years 1980 and 1998, there were 21 definite cases of invasive pulmonary aspergillosis and four probable. The median time to onset was 46 days. The presentation and diag-

nostic features included fever/cough, single or multiple pulmonary nodules, abnormal radiological findings (nodules), and a positive culture. Neutropenia was not present (Montoya et al. 2003).

Further information on aspergillosis in solid organ transplant recipients can be found in Kubak (2002) and Singh (2003).

Invasive aspergillus infection in AIDS

Invasive aspergillus infections appear to be rather uncommon in individuals with AIDS, although the incidence appears to be increasing (Minamoto et al. 1992; Lortholary et al. 1993; Khoo and Denning 1994). The rarity of invasive aspergillosis during the first few years of the AIDS epidemic led to its exclusion as an AIDS-defining illness. The low incidence of this infection in patients with AIDS is highlighted by the report from the Memorial Sloan Kettering Cancer Center, New York (Pursell et al. 1992). Of the 972 patients with AIDS who were observed over a 10-year period, *Aspergillus* spp. were isolated from various respiratory sites from 45 patients before death. Invasive aspergillosis was documented postmortem in four of these patients and was strongly suspected in an additional patient in whom a postmortem examination was not performed. Traditional risk factors for the development of invasive disease (neutropenia, hematological malignancy, and/or corticosteroid use) were present in all the patients with invasive aspergillosis. A review of the literature up to 1992 reveals reports of 13 cases of invasive aspergillosis in patients with AIDS.

In a report from France (Daleine et al. 1993) where respiratory secretions from 614 patients positive for the human immunodeficiency virus (HIV) over a 2-year period were analyzed retrospectively, it was found that the prevalence of *Aspergillus* spp. isolated was 2.7 percent in BAL specimens (21 of 757), 15.1 percent in sputum specimens (3 of 53), 12.6 percent in bronchial aspirates (11 of 87), 7 percent in protected brush specimens (2 of 28) and 16.6 percent in lung biopsy specimens (4 of 24). A total of 20 patients (rate = 3.14 percent) had lung specimens positive for *Aspergillus* spp.

Patients with advanced HIV infection certainly have profound underlying immunosuppression and are exposed to aspergillus conidia, so it would appear that these infections should be more common. One explanation for the low prevalence may be the fact that neutrophils and macrophages are the main immunological defenses against *Aspergillus* spp. and that these components of the host defense system are more or less spared in HIV infection compared with the defects in T lymphocytes. However, in vitro, neutrophils from children with HIV appear to show impaired ability to kill hyphae of *A. fumigatus* (Roildes et al. 1993a).

One explanation may be that these infections are now being diagnosed more frequently than in the past because of less reluctance to perform bronchoscopies and lung biopsies. Other explanations may relate to an increased prevalence of risk factors for invasive aspergillosis in the HIV-infected population. One consideration is whether advanced HIV infection itself is a risk factor, and whether certain pulmonary infections, such as tuberculosis or *Pneumocystis carinii* pneumonia, may lead to pulmonary damage that predisposes to invasive aspergillosis. Aerosolized pentamidine may also be a risk factor, because most patients with invasive aspergillosis reported in the literature had received this form of therapy. Finally, it should be considered whether prolonged treatment with certain antifungal agents having little activity against *Aspergillus* spp., and thus possibly leading to colonization, is an additional risk factor. It must be emphasized, however, that, as yet, there is little to support the establishment of anything but neutropenia and steroid treatment as risk factors for invasive aspergillosis infection in people infected with HIV.

The clinical presentation of invasive aspergillosis in the HIV-infected population ranges from isolated cutaneous involvement to widely disseminated disease. Most patients reported thus far have advanced HIV infection, with CD4 counts below 50/mm^3 and histories of other opportunistic infections. Pulmonary infections are the most common manifestation of invasive aspergillosis in patients with AIDS (Miller et al. 1994). The lungs are involved as the sole site in about 60–80 percent of all cases, and lung involvement with extrapulmonary disease occurs in about 25 percent. Extrapulmonary infection in the absence of lung involvement has been seen in about 10–15 percent of cases.

Extrapulmonary invasive aspergillosis has been seen in virtually all organs of the body in patients with AIDS (Kempner et al. 1993). The most common site has been the CNS (Woods and Goldsmith 1990); focal abscesses, meningitis, and spinal cord lesions have all been described. Only a few patients with CNS lesions have been intravenous drug users; most probably result from hematogenous spread, presumably from the lungs, but there is an occasional case in which it seems likely that spread from the sphenoid sinus occurred, with resulting basilar meningitis. The heart has been the next most commonly involved extrapulmonary organ; many pathological descriptions have shown multiple myocardial abscesses. Gastrointestinal aspergillosis has been described in one patient, with scattered ulcers extending from the stomach to the colon. Abscesses of the kidney, liver, spleen, and peripancreatic spaces have all been reported in the literature; most were diagnosed postmortem.

Invasive pulmonary aspergillosis in neonates

Only a few cases of invasive aspergillosis have been reported in neonates and infants <3 months of age. A

case report from Frankfurt, Germany reviews 43 cases of invasive aspergillosis during the period 1955–96 (Groll et al. 1998a). Eleven of the 44 patients had primary cutaneous aspergillosis, 10 had invasive pulmonary aspergillosis, and 14 had disseminated disease. Most infections were nosocomial in origin. Prematurity (43 percent), proven chronic granulomatous disease (14 percent), and a complex of diarrhea, dehydration, malnutrition, and invasive bacterial infection (23 percent) accounted for the majority of underlying conditions. At least 41 percent of the patients had received corticosteroid therapy before diagnosis, but only one patient had been neutropenic. Among patients who received medical and/or surgical treatment, outcome was relatively favorable, with an overall survival rate of 73 percent. From this review it is evident that invasive aspergillosis may occur in neonates and young infants. The current recommendation regarding treatment is high-dose amphotericin B and appropriate surgical interventions.

A North American experience of aspergillosis in children is illustrative (Abbasi et al. 1999). Sixty-six patients with culture-documented aspergillus infection were identified from a 34-year period. The most common underlying diagnosis was leukemia. Risk factors included neutropenia, immunosuppression, and prior antibiotic therapy. On the basis of clinical presentation, 23 patients were believed to have disseminated disease and 43 to have localized disease. The lung was the most frequently affected organ. Overall mortality was 85 percent within the first year of diagnosis. Patients who presented with disease in sites other than the lungs fared better than patients with initial pulmonary involvement. A further North American experience is reviewed by Wright et al. (2003).

EPIDEMIOLOGY OF ASPERGILLOSIS

Aspergillus spp. grow well on virtually any organic debris. They are, therefore, found naturally in leaves, grains, soil, and composts. Compost is a particularly rich source for the thermotolerant species. *A. fumigatus* is often the predominant fungal member of the compost microbiota, with more than 10^8 conidia per gram of compost material. Likewise, numbers of airborne conidia in such places as hay barns have been estimated to be as high as $10^9/m^3$. These numbers are exceptional, however, and the number of conidia in outdoor air probably rarely exceeds $200/m^3$. Interestingly, indoor air usually contains larger numbers of aspergillus conidia than outdoor air sampled over the same period. This has led hospital epidemiologists to advocate the use of high-efficiency filtration units to reduce to undetectable levels the number of airborne particles in the rooms of patients at risk. Various hospital routines may increase the level of contamination. Bursts of airborne conidia have, for example, been detected during cleaning procedures (Rhame et al. 1984). In general, however, with the exception of those individuals with occupational exposure, everyday exposure to conidia of *Aspergillus* spp. may be of little concern to most of the population. Nosocomial outbreaks of invasive aspergillosis are often attributed, correctly or incorrectly, to an environmental point source, such as a contaminated air vent or a demolition project (Walsh and Pizzo 1988; Walsh and Dixon 1989). The interrelationship between isolates of *A. fumigatus* from outside air with strains implicated in clusters of invasive disease has been analyzed by various molecular techniques (Loudon et al. 1993, 1994; Symoens et al. 1993; Girardin et al. 1994b; Goodley et al. 1994; Tang et al. 1994; Kennedy et al. 1995; Anderson et al. 1996).

HOST DEFENSE

Host defense to invasive aspergillosis is primarily an innate mechanism. By contrast, in the allergic forms of aspergillosis, the acquired responses appear to contribute more to the pathology than to the control of disease. In immunocompromised patients, various defects in neutrophil function have been recognized in, for example, patients with chronic granulomatous disease or patients with prolonged neutropenia induced by cytotoxic drugs. Elucidation of the host defense mechanisms in aspergillosis has been the focus of many studies (reviewed by Rhodes 1993, Kauffman and Tomee 2002).

Innate mechanisms

COLONIZATION OF THE RESPIRATORY MUCOSA

Initial interaction with host cells and colonization of mucosal surfaces are now considered crucial steps in the establishment of infection. Ligand-mediated adherence may be a component of this process. For example, fibrinogen, which plays a key role in inflammatory reactions and in the coagulation pathway, appears to be a good candidate for mediating adherence. Various studies have shown that, among filamentous fungi belonging to different groups (opportunistic fungi, strictly saprophytic or phytopathogenic fungi, and dermatophyte or related species), only the pathogenic aspergilli, particularly *A. fumigatus*, bind crude fibrinogen (reviewed by Bouchara et al. 1988, 1995, and Annaix et al. 1992). The binding was detected mainly at the surface of the conidia. Further studies demonstrated that the site of maximum fibrinogen binding was on the outer conidial surface but that binding sites also lay in the inner part of the wall and in cytoplasmic granules (Annaix et al. 1992). Other virulence determinants of *A. fumigatus*, relevant in vivo, may include proteases and elastase enzymes (Kolattukudy et al. 1993; Jaton-Ogay et al. 1994; Bouchara et al. 1995).

Aspergillus spp., unlike many other fungal species, can colonize the respiratory mucosa. This can occur in the normal airway, and the individual may become sensitized, causing ABPA (see section on Allergic aspergillosis below). More commonly, the fungus colonizes damaged airways, such as in patients with healed tuberculosis, bronchiectasis, and cystic fibrosis (see section on Allergic aspergillosis below). Although the type III hypersensitivity reaction to aspergillus antigens in the bronchial wall in ABPA and the importance of the neutrophil in host defense against *Aspergillus* spp. are well appreciated (see section on Immune response below), the mechanisms of colonization of the respiratory mucosa are poorly understood. Amitani and colleagues (1992) have shown that culture filtrates of most clinical isolates of *A. fumigatus* studied slow ciliary beat frequency and damage human respiratory epithelium in vitro. These changes appeared to occur concurrently. The characteristics of a factor purified from a culture filtrate of one clinical isolate of *A. fumigatus* has been described (Amitani et al. 1995). The ciliary-inhibitory activity was heat labile and associated with both high- and low-molecular-weight factors. As a result of purification of the low-molecular-weight activity, one such component was identified as gliotoxin, a known metabolite of *A. fumigatus*. It is suggested that *A. fumigatus* produces a number of biologically active substances which slow ciliary beating and damage epithelium and which may influence colonization of the airways.

INTERACTION WITH ALVEOLAR MACROPHAGES AND POLYMORPHONUCLEAR LEUKOCYTES

Numerous reviews of the acquisition and pathogenesis of invasive aspergillosis have identified common features which appear to be responsible for placing patients at risk for these infections (Holden et al. 1994). Neutropenia and broad-spectrum antibiotics and corticosteroids are consistently identified as key predisposing factors. Likewise, the recognition that patients with chronic granulomatous disease, in which phagocytic cells fail to produce the respiratory burst, are susceptible to invasive aspergillosis adds further weight to the concept that the presence of normally functioning phagocytes is the key factor in defense against invasive disease. It has been shown, in a murine model, that both neutrophil and monocyte function have to be ablated for invasive infection to develop. Bronchoalveolar macrophages are believed to serve as the first line of defense and to be responsible for the ingestion and intracellular killing of inhaled conidia (Henwick et al. 1993). Those conidia escaping the macrophages and going on to germinate and form hyphae are the target of attack by the granulocytes, which adhere to the hyphae, degranulate, and kill the fungus.

Our knowledge of the role that phagocytic cells play in the eradication of *A. fumigatus* has been advanced only recently. The published studies on the ability of phagocytic cells to kill conidia of *A. fumigatus* have produced divergent and conflicting results, largely as a result of the many different in vitro assays of phagocytosis and intracellular killing being used (Ibrahim-Granet et al. 2003).

One important aspect of host defense to *Aspergillus* in relation to phagocytosis in the alveoli may be the role of surfactant proteins. Surfactant protein A (SP-A) and surfactant protein D (SP-D) are thought to play important roles in pulmonary defense. These proteins are members of the C-type lectin superfamily, which also includes serum mannose-binding protein, conglutinin, and collectin 43. SP-A and SP-D are synthesized by type II cells and Clara cells in the lung and share many structural features. The host defense role played by SP-A and SP-D very much depends on the target organs and specific surfactant protein involved. Recent reports have shown that these proteins bind to and enhance killing and clearance of the organism in vitro (Madan et al. 1997; Allen et al. 1999). It is suggested that SP-D specifically plays a major role in the recognition of *Aspergillus* conidia in alveolar fluid (Allen et al. 1999).

ANTIPHAGOCYTIC ACTIVITY OF *ASPERGILLUS*-DERIVED PRODUCTS

It has been shown over the past 10 years that spores and spore diffusates of *A. fumigatus* suppress the production of superoxide anion and hydrogen peroxide by rodent phagocytic cells and that diffusates of *A. fumigatus* spores inhibit phagocytosis of antibody-coated radiolabeled sheep red blood cells by mouse peritoneal exudate cells. Similar experiments with human cells have shown that spore diffusates of *A. fumigatus* reduce the migration of human polymorphonuclear leukocytes (PMNL) and decrease the capacity of mouse peritoneal exudate cells to spread on glass. In addition, it has been shown that human pulmonary macrophages can bind and kill *A. fumigatus* conidia. More recently, Murayama and colleagues (1998) showed that *Aspergillus*-derived products had a suppressive effect on PMNL-mediated damage of *A. fumigatus* hyphae. The conclusion drawn from these studies is that *A. fumigatus* produces a variety of substances, some of which may suppress antifungal (anti-*A. fumigatus*) activity of human alveolar macrophages and PMNLs.

RECENT PROGRESS IN AN UNDERSTANDING OF HOST DEFENSE MECHANISMS AGAINST INVASIVE ASPERGILLOSIS

The fact that invasive aspergillosis disproportionately afflicts immunocompromised patients indicates the critical importance of the immune status of the host in this infection, but the defense mechanisms against this pathogen remain incompletely understood. Recent work suggests that the chemokine ligand monocyte chemotactic protein-1, also designated CC chemokine ligand-2 (MCP-1/CCL2), may be necessary for effective host defense against invasive aspergillosis (Morrison et al.

2003). It was found that there was a rapid and marked induction of MCP-1/CCL2 in the lungs of neutropenic mice with invasive aspergillosis. Neutralizing MCP-1/CCL2 resulted in twofold greater mortality and greater than threefold increase in pathogen burden in the lungs. Neutralization of MCP-1/CCL2 also resulted in reduced recruitment of natural killer (NK) cells to the lungs at early time points, but did not affect the number of other leukocyte effector cells in the lungs. Ab-mediated depletion of NK cells similarly resulted in impaired defenses against the infection, resulting in a greater than twofold increase in mortality and impaired clearance of the pathogen from the lungs. This study suggests that MCP-1/CCL2-mediated recruitment of NK cells to the lungs may be a critical early host defense mechanism in invasive aspergillosis and indicates that NK cells may be an important and previously unrecognized effector cell in this infection.

Another area of innate host defenses against *Aspergillus* are defensins. Defensins and other antimicrobial peptides act in the innate defense of epithelial surfaces. Human β-defensin 1 (hBD-1) has recently been shown to be expressed in airway epithelial cells and so has been implicated as a primary component of antibacterial activity in human lung. β-Defensins have been implicated in host defense of human airway epithelia. Antibacterial activity associated with low-molecular-weight, salt-sensitive, and heat-stable factors has been detected in the surface fluid of primary cultures from normal airway epithelia, and expression of hBD-1 messenger RNA has been detected in human lung. Hence, hBD-1 has been implicated as a major component of host defense in human airways. Furthermore, inactivation of hBD-1 in the lungs of cystic fibrosis patients may be an important cause for the onset of chronic lung infection. It is tempting to speculate that β-defensins have a role to play in the pathogenesis of pulmonary aspergillosis. Research in this area is continuing.

Modulation of innate mechanisms

There has been some concern expressed regarding the immunosuppressive effects of cyclosporin A on the function of peripheral blood phagocytes. Cyclosporin A has been reported to induce immunosuppressive effects on the fungicidal activity of murine polymorphonuclear monocytes against blastoconidia of *Candida albicans* in vivo and has rendered the animals susceptible to subsequent challenge with this organism (Vecchiarelli et al. 1989; Roildes et al. 1993b, c). Roildes et al. (1994a, b) addressed this issue by looking at the effects of cyclosporin A on phagocytic defenses against *A. fumigatus* in vitro and ex vivo. Cyclosporin A at therapeutically relevant concentrations did not suppress antifungal activity of phagocytes except that of circulating monocytes. However, cyclosporin A did appear to induce significant immunosuppression of phagocytes' antifungal function at relatively high concentrations in vitro, especially when combined with corticosteroids. This observation has potential implications for patients receiving these immunosuppressive agents.

Treatment with recombinant human interferon-γ is known to augment the ability of monocytes and neutrophils from patients with chronic granulomatous disease (CGD) to generate superoxide. This observation prompted Rex et al. (1990) to look at the effect of interferon-γ on neutrophils, from patients on interferon-γ therapy for CGD, in their ability to damage aspergillus hyphae. Neutrophils from patients receiving interferon-γ produced significantly more damage to hyphal elements than those from the placebo group. The authors conclude that interferon-γ therapy improves the ability of CGD neutrophils to damage *A. fumigatus* hyphae in an in vitro assay.

Immune response

In colonizing and in invasive forms of aspergillosis, the study of the immune response has centered on the humoral response as an aid to determining the diagnosis or prognosis of patients. In ABPA, studies have attempted to explain the pathology of the disease, which appears to be caused primarily by that very response. In all studies on the humoral response to aspergillus antigens, progress has been hampered by the lack of common, reference antigens which are capable of detecting responses to all common species and by which results obtained in multiple centers may be compared.

HUMORAL RESPONSE IN ALLERGIC ASPERGILLOSIS

Patients with extrinsic allergic alveolitis or hypersensitivity pneumonitis develop IgG precipitin antibodies. The pulmonary pathology appears to be mediated by immune complex deposition, perhaps in conjunction with cell-mediated mechanisms. By contrast, IgE appears to play a major role in the pathophysiology of ABPA. The patients have elevated total IgE, which rises and falls with exacerbations and remission of clinical symptoms. Specific anti-aspergillus IgE is also demonstrable in ABPA patients and IgG anti-aspergillus precipitin antibodies are also produced by ABPA patients, with almost 100 percent having positive serological tests for these antibodies (Brummund et al. 1987). Pulmonary immune complex deposition, secondary to elevated IgG antibodies, may account for much of the inflammatory component seen during active phases of ABPA.

Significantly elevated levels of specific *A. fumigatus* IgG have been also been detected in cystic fibrosis patients with ABPA (Murali et al. 1994).

HUMORAL RESPONSE IN ASPERGILLOMA

Patients with aspergilloma, almost without exception, mount a strong IgG response to aspergillus antigens,

judging by the multiple precipitin bands formed on agar gel double diffusion or counterimmunoelectrophoresis to extracts of the infecting fungus. The response does not appear to provide any protection to the patient, however. In cases of aspergilloma in which the fungus ball has formed secondary to cavitation of an invasive lesion, the ability of patients to produce antibodies is governed more by their degree of immunosuppression than by the type of disease.

HUMORAL RESPONSE IN INVASIVE ASPERGILLOSIS

As a result of their profound degrees of immunosuppression, patients with invasive aspergillosis mount little to no humoral response to the fungus when the standard serological tests are used. However, the use of purified antigens in immunoblotting procedures appears to detect antibody in immunocompromised individuals (Hearn et al. 1995). Antibody responses in these patients do not appear to confer any degree of protection in invasive aspergillosis.

CELLULAR RESPONSE IN ALLERGIC ASPERGILLOSIS

The presence of bronchocentric granulomatosis as a pathological hallmark of ABPA indicates that there must be a cell-mediated component in the response of these patients to *Aspergillus* spp. Lymphocyte proliferation in response to antigens of *A. fumigatus* has been demonstrated in some ABPA patients. Likewise, fractionation of antigenic extracts of *A. fumigatus* yielded components that elicited positive-type (type IV) skin reactivity in, and proliferation of lymphocytes from, sensitized guinea pigs.

CELLULAR RESPONSE IN ASPERGILLOMA

There is little evidence to support the presence of a cell-mediated response in aspergilloma patients. In general, the pathology of aspergillomas is one in which an inflammatory response, either acute or chronic, is minimal. Host defense against this form of infection has not been well studied.

CELLULAR RESPONSE IN INVASIVE ASPERGILLOSIS

The fungicidal activity of neutrophils against hyphae involves the release of granular contents on the surface of the organism. Both macrophages and neutrophils use oxidative and non-oxidative fungicidal mechanisms including myeloperoxidase and myeloperoxidase-independent oxidants. The granular constituents of neutrophils have all been implicated as antifungal agents and include: lactoferrin, lysozyme, cathepsin G, azarocidin, and defensins. Interferon-γ and granulocyte-macrophage colony-stimulating factors (GM-CSF) both augment oxidant release and fungicidal activity. Specific antibodies or T lymphocytes do not appear to be of major importance in host protection against *Aspergillus* spp. Complement facilitates neutrophil damage to hyphae and monocyte killing of conidia.

The role of T cells in invasive disease has been investigated in experimental systems, with little consensus as to its importance. For example, nu/nu mice fare no worse than their nu/+ littermates when infected with conidia of *A. fumigatus*. Nu/+ can be immunized protectively against the fungus, however, and the protective immunity can be transferred to nu/nu mice recipients with adherent peritoneal cells from the immunized nu/+ mice. This suggests a role for T cells and macrophages in the acquisition of immunity to aspergillosis, but the issue is still open to investigation. In humans, reviews of cases of invasive aspergillosis have not suggested that T-cell defects were primary predisposing factors for disease but rather that granulocytopenia is the risk factor most commonly associated with infection. Additional recent evidence on the incidence of invasive aspergillosis in patients with AIDS also suggests that, even in the face of profound loss of CD4+ T cells, this fungal infection rarely occurs (see above), except when patients become neutropenic, secondary to azidothymidine (AZT) therapy.

Immune regulation in aspergillosis

Regulation of the immune response to aspergillosis has been little studied. Of interest are the descriptions of metabolic products of the fungus that are immunomodulatory in vitro. One of the best characterized of these is gliotoxin, produced in vitro by *A. fumigatus*. Gliotoxin is a potent inhibitor of macrophage phagocytosis and also appears to inhibit the ability of spleen cells to induce major histocompatibility complex (MHC)-restricted cytotoxic cells. *A. fumigatus* also produces phospholipid compounds that are active in inhibiting the activation of complement via the alternative pathway. These factors have the potential to influence both the innate and immune responses that provide adequate host defense to *Aspergillus* spp. in the normal host. It is not known whether gliotoxin or the complement inhibitor is, however, produced in biologically significant quantities in vivo.

DIAGNOSIS

Establishing the diagnosis of aspergillosis in a compromised patient is difficult because the clinical presentation is nonspecific and the fungus is seldom isolated from blood or other body fluids, or from sputum. Interpretation of serological test results is also difficult because failure to detect precipitins in a compromised individual does not mean that aspergillosis is not present (Saugier-Veber et al. 1993). Nor is the detection of circulating antigen a consistent finding in such patients (Jones and McLintock 2003; McLintock and Jones 2004).

The problems associated with the diagnosis of invasive aspergillosis are highlighted by the diagnostic criteria that have to be fulfilled before patients are eligible for inclusion in clinical trials of new antifungal agents. Very often these criteria are either presumptive or definitive depending on whether tissue diagnosis has been achieved. The following patient selection criteria are required by the European Organization for Research in the Treatment of Cancer (EORTC):

- persistence of fever: ⩾38°C for 3–5 days despite broad-spectrum antibiotics, unless biopsy-proven aspergillosis is documented before day 5 of fever
- current negative blood cultures for bacterial pathogens
- no presumptive diagnosis of infections caused by viruses, acid-fast bacilli, legionellae, Q fever, psittacosis, mycoplasmas, chlamydia pneumonia, and *Pneumocystis* sp.
- appropriate physical symptoms and signs suggestive of invasive aspergillosis such as:
  pulmonary: cough, dyspnea, hemoptysis, crepitation, hypoxia, chest pain
  sinus: headache, nasal discharge, facial swelling, tenderness, cellulitis
  liver: may be asymptomatic, discomfort in the right upper quadrant, jaundice, hepatomegaly, abnormal liver function tests
  CNS: headache, focal fits, focal neurological deficit, confusion, altered conscious level, abnormal CSF findings
  other sites: these include bone, kidney, skin, pleura, eyes, spine, external ear, endocarditis, pericardium, joints, adrenal, peritoneal, gastrointestinal tract, lymph node, and thyroid, as appropriate
- appropriate radiological investigations:
  pulmonary: pulmonary infiltrates either nonspecific or suggestive (nodules, cavities)
  sinus: mucosal thickening, opacification/clouded sinus spaces, fluid levels, bone destruction
  liver: nodules/abscesses demonstrated by computed tomography, ultrasonography, or MRI
  spleen: nodules/abscesses demonstrated by computed tomography, ultrasonography, or MRI
  CNS: nodules/abscesses demonstrated by computed tomography, ultrasonography, or MRI
  other sites: as appropriate
- positive identification of *Aspergillus* spp. either by histology or by culture from an appropriate site (i.e. involved organ):
  pulmonary: bronchial washing/bronchoalveolar lavage/tracheal aspirate/anterior nares/transbronchial biopsy/radiologically guided fine-needle aspiration (FNA)/open lung biopsy
  sinus: nasal eschars/sinus aspirate/sinus biopsy
  liver: FNA/laparotomy/laparoscopic guided biopsy
  spleen: FNA/laparotomy/laparoscopic guided biopsy
  CNS: FNA/stereotactic biopsy, CSF
  other sites: appropriate sampling.

A positive blood culture (highly unlikely in aspergillosis) in the presence of radiological and clinical features can be used as an alternative mycological confirmation.

Entry into clinical trials often depends on direct tissue evidence but obviously some patients will be too ill or considered at high risk (thrombocytopenia) for invasive procedures, e.g. open lung biopsy.

Definitively diagnosed invasive aspergillosis requires all of the above criteria to be satisfied and *Aspergillus* spp. should be isolated from the organ/site involved.

Microscopy

Microscopic examination of sputum preparations is often helpful in the diagnosis of allergic aspergillosis, because abundant septate mycelia with characteristic dichotomous branching are usually seen.

Microscopic examination of sputum is seldom helpful in patients with suspected invasive aspergillosis, but examination of BAL specimens is often rewarding (Delvenne et al. 1993) (Figure 11). Typical mycelium may also be detected in wet preparations of necrotic material from cutaneous lesions or sinus washings, but isolation of the etiologic agent in culture is essential to confirm the diagnosis.

The most reliable method for the diagnosis of acute invasive aspergillosis is the examination of stained tissue sections. The detection of nonpigmented, septate filaments which show repeated dichotomous branching is characteristic of aspergillus infection (Figures 12, 34.13 and 34.14). However, other less common organisms, such as *Fusarium* spp. and *Scedosporium apiospermum*, appear similar. More precise identification can sometimes be achieved with immunochemical staining methods. One of the main limitations in using this approach has been crossreactivity between species, and even monoclonal antibodies may suffer the same problems. In one report it has been shown that murine monoclonal antibodies specifically recognize cytoplasmic antigens of *A. fumigatus*, *A. flavus*, and *A. niger*

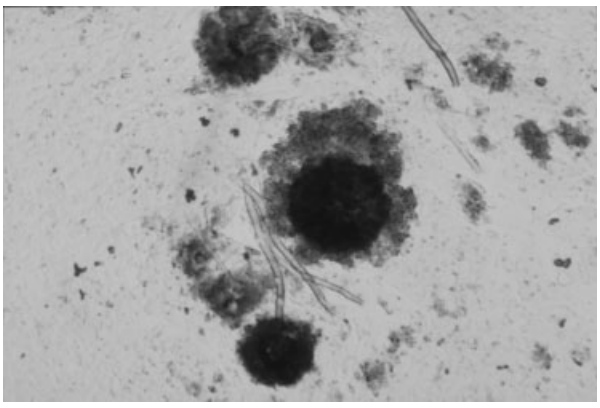

Figure 11 *Direct microscopy of sputum from a patient with allergic bronchopulmonary aspergillosis caused by* A. niger

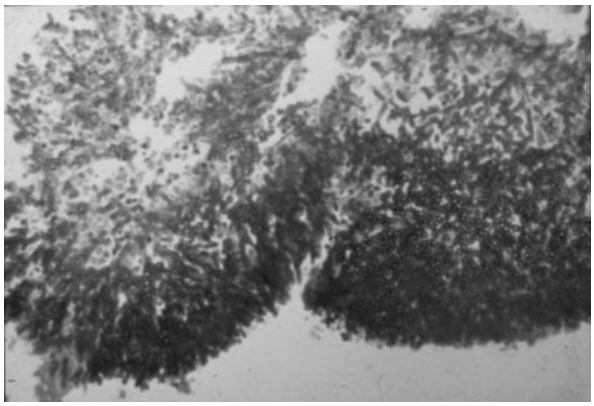

Figure 12 *Histopathological appearance of an aspergilloma*

(Fenelon et al. 1999). These antibodies were used to identify *Aspergillus* spp. in frozen sections of tissue from cases of invasive aspergillosis by immunofluorescence, and in paraffin-embedded clinical specimens by immunofluorescence and immunoperoxidase staining.

Optical brighteners, such as Calcofluor white, which label glucan and chitin in the fungal cell wall, have been used to highlight fungal elements in a variety of clinical specimens for the past 20 years. Further refinements to this technique for the recognition of aspergillus hyphae in respiratory secretions have been reported by Ruchel and Schaffrinski (1999).

Culture

The definitive diagnosis of aspergillosis depends upon the isolation of the etiologic agent in culture. The fungus may be recovered from sputum specimens from patients with allergic aspergillosis, but cultures from patients with other forms of aspergillosis are less successful. Moreover, because *Aspergillus* spp. are commonly found in the air, their isolation must be interpreted with caution (Nalesnik et al. 1980). Their isolation from sputum is more convincing if multiple colonies are obtained on a plate, or the same fungus is recovered on more than one occasion. Often the number of colonies isolated is small which may result from the filamentous character of the organism. Positive culture may also be a sign of transient exposure to inhaled spores. If sputum cannot be obtained from an immunocompromised patient with a lung infiltrate, alveolar lavage specimens should be obtained. Isolation of an *Aspergillus* sp. from such specimens is often indicative of infection, but is positive in less than 60 percent of cases. *Aspergillus* spp. may be recovered from sputum or bronchial lavage specimens, especially in patients with diffuse pulmonary infiltrates, whereas recovery of fungus from patients with focal lesions is more difficult. A positive culture is indicative of infection but may also merely represent colonization (Delvenne et al. 1993). However, the isolation of *A. fumigatus* from respiratory tract specimens in heart transplant recipients is highly predictive of invasive aspergillosis (Munoz et al. 2003). It has been estimated that around 40 percent of neutropenic patients from whom *Aspergillus* spp. are isolated do not have invasive disease (McWhinney et al. 1993).

Aspergillus spp. are seldom recovered from blood, urine, or CSF specimens, although cultures of blood have been positive in occasional patients with endocarditis. More often, however, their isolation is the result of contamination. It has not been established whether lysis-centrifugation is any more useful than traditional blood culture methods in the diagnosis of aspergillosis.

The diagnosis of aspergillus sinusitis is less difficult to establish than infection of other sites. The fungus can usually be isolated from sinus washings or biopsies of the necrotic lesions in the nose or palate.

Skin tests

Skin tests with *A. fumigatus* antigen are useful in the diagnosis of allergic aspergillosis. Patients with uncomplicated/extrinsic asthma caused by *Aspergillus* spp. give

an immediate type I reaction. Those with allergic bronchopulmonary aspergillosis give an immediate type I reaction and many also give a delayed type IV reaction.

Serological tests

Many potential systems for the immunodiagnosis of aspergillosis have been described (Kurup and Kumar 1991; Barnes 1993; Kappe and Seeliger 1993). Those based on detection of antibody to the organism have been very successful in allergic aspergillosis and aspergilloma, and those used for the detection of fungal antigen have great potential for the diagnosis of invasive aspergillosis (Manso et al. 1994). To understand the potentials and limitations of serology in aspergillosis, it is necessary to review the extensive literature on the antigens of *Aspergillus* spp. and how this knowledge has been applied to the design of immunoassays for improved diagnosis.

ANTIGENS OF *ASPERGILLUS* SPP.

A major problem that has prevented the development of standardized serological tests is the vast heterogeneity of antigen types and the lack of understanding of their relevance in vivo. Most of the antigens identified in crude extracts from *A. fumigatus* grown in vitro lack specificity (Hearn 1992; Latgé et al. 1993). For example, Western blot experiments have demonstrated that circulating antibodies from sera of either aspergilloma patients or non-infected individuals bind to most antigens secreted in glucose–peptone culture medium (Latgé et al. 1993). In this study, the levels of anti-*A. fumigatus* antibodies were 10–100 times higher in aspergilloma patients than in control individuals. Furthermore, antigens of *A. fumigatus* crossreact with other fungi (Kumar and Kurup 1993).

The presence of detectable levels of anti-*Aspergillus* spp. antibodies in every individual is thought to result from the continuous inhalation of conidia from the atmosphere. However, normal individuals inhale only conidia whereas the development of aspergillosis results from mycelial growth in lung tissue. Although conidial and mycelial antigens are very similar, growth-phase-specific antigens have been demonstrated in *Aspergillus* spp. (Kauffman et al. 1984). In addition, expression of different mycelial antigens in vitro is highly dependent on the nutrient composition of the culture medium (Moutaouakil et al. 1993). These findings suggest the existence of antigens, released during mycelial growth in vivo, which can only be recognized by antibodies in patients infected with *Aspergillus* spp. To identify such antigens, Sarfati et al. (1995) probed immunoblots of extracts from kidneys of mice infected intravenously with *A. fumigatus* with sera from patients with aspergilloma. A limited number of antigens were detected with molecular masses of 31, 36, 56, 84, 88, and 200 kDa. A 88 kDa antigen secreted by *A. fumigatus* has been described by Kobayashi et al. (1993). Antigens of this type have been characterized as belonging to two classes:

1. galactomannan- and/or galactofuran-containing glycoproteins
2. antigenic proteins without the galactofuran epitope.

These studies have confirmed that antigens bearing a galactofuranosyl epitope are present both in vivo and in vitro. An exhaustive review of *Aspergillus* antigens can be found in Latgé (1999).

TESTS FOR ANTIBODIES TO *ASPERGILLUS* SPP.

Detection of specific precipitating antibodies to *Aspergillus* spp. by double diffusion, counterimmunoelectrophoresis or enzyme-linked immunosorbent assay (ELISA) has provided the basis for the most frequently used serological tests for the diagnosis of aspergillosis (Hopwood and Evans 1991; Barnes 1993). Some of the tests are available commercially from a number of sources and are technically simple to perform and to interpret. The presence of one or more weak precipitin bands is one of the diagnostic criteria accepted for the diagnosis of ABPA. Published studies would suggest that 70–100 percent of patients with ABPA are positive for IgG-precipitating antibodies directed against *Aspergillus* spp., depending on the antigen used and whether or not serum was concentrated before testing. Furthermore, specific IgE is a reliable indicator of ABPA in cystic fibrosis (Marchant et al. 1994). In addition, rates of positivity in patients with extrinsic allergic alveolitis are also very high. Precipitins are present in 98–99 percent of aspergilloma patients, and multiple bands, often three or more, are routinely present. In patients with invasive aspergillosis, however, the experience with detecting precipitating antibodies has been disappointing. Immunoblotting is a sensitive technique that has been used to detect antibodies in sera from patients with invasive aspergillosis and patients with ABPA. Although the correlation between the sizes of the recognized antigens has not been exact, it has great research potential for determining which antigens may be the most appropriate for future testing. This information, in conjunction with ELISA data, may allow wider availability of a more sensitive and specific test for aspergillosis.

More recently, a number of highly sensitive methods for the detection of very low levels of antibodies in serum samples have been described. It has been reported that all serum specimens from patients with invasive aspergillosis contain antibodies to a 58 kDa concanavalin A-binding antigen identified by sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and immunoblotting. However, the specificity of this antigen has not been well documented (Fratamico and Buckley 1991). Both antigen and antibody levels have been monitored successfully in a number of cases

of invasive aspergillosis (Manso et al. 1994; Hearn et al. 1995). With these highly sensitive methods for antibody detection, a problem of specificity arises because IgG antibodies to aspergillus antigens can be detected in a proportion of healthy individuals.

Immunoblotting in conjunction with SDS-PAGE has been used to detect serological responses to aspergillus antigens. Piechura and coworkers (1985) have used two-dimensional electrophoresis and isoelectrofocusing to analyze complex mixtures of aspergillus antigens. Hearn et al. (1995) have extended these studies by using immunoblotting to detect specific IgG antibodies to aspergillus antigens in serum specimens from patients with different types of aspergillosis. Different *A. fumigatus* extracts, including culture filtrates, surface components, and mycelial fractions, were tested. All these preparations were shown to be highly reactive antigenically when tested previously by precipitin and ELISA procedures. In particular, patients with invasive aspergillosis were capable of mounting a response to culture filtrates, surface washes, and mycelial extracts of *A. fumigatus* (a total of 12 antigenic fractions); 11 were reactive with serum specimens from patients with aspergilloma. Eight of these antigens showed good responses with serum specimens from patients with ABPA, which were used to assess the sensitivity of IgG detection. No measurable activity was detected in 18 negative control serum specimens, whereas 11 of 13 patients with proven, highly probable, or probable cases of invasive aspergillosis had anti-*Aspergillus* spp. IgG to multiple antigenic preparations. Patients with invasive aspergillosis who were capable of mounting a substantial humoral response to aspergillus antigens gave an antibody profile with five antigenic preparations, which seemed to be characteristic of the disease. The authors concluded that this approach was highly sensitive and may allow the selection of fractions that are both highly antigenic and specific for the detection of antibody to aspergillus antigens. This study also indicates that the use of a spectrum of antigenic molecules is advisable, given the variability observed in the immune responses of individual patients.

DETECTION OF ASPERGILLUS ANTIGEN

Antibody production in the immunocompromised host with invasive aspergillosis is invariably difficult to detect. Therefore, methods have been sought for diagnosing this infection which would rely on the measurement of a cell component of fungal origin and thereby be independent of the host's ability to respond (Richardson 1987; Barnes 1993). Aspergillus galactomannan circulates during infection and appears in the urine, presumably after clearance by a receptor-mediated process by Kupffer's cells in the liver. In addition to galactomannan, at least seven other *Aspergillus*-related antigens have been detected, by immunoblotting, in the urine of patients with invasive disease (Ansborg et al. 1994).

Various immunoassay formats have been designed to detect antigen, either free or in immune complexes in serum, bronchoalveolar fluid, or urine. In two of the largest studies on patient samples, a radioimmunoassay for antigen detection showed 74 percent sensitivity and 90 percent specificity, and either of two ELISA procedures used to measure antigenemia or antigenuria, with a rat monoclonal antibody (EB-42) specific for galactomannan, showed greater than 95 percent sensitivity and specificity. The value of granulocyte-macrophage (GM) detection by the Pastorex *Aspergillus* latex agglutination (LA) test (Sanofi Diagnostics Pasteur, Marnes-La-Coquette, France) has been evaluated by a number of groups (Haynes and Rogers 1994; Hopwood et al. 1995; Verweij et al. 1995a, b, c) and the test showed sensitivities of up to 95 percent with serum samples from patients with a high index of suspicion for invasive aspergillosis. The latex test was also found to yield positive results earlier than conventional microbiological procedures for 68 percent of patients with proven invasive aspergillosis. However, these observations have not been confirmed by others (Warnock et al. 1991), and a sensitivity as low as 38 percent has been reported (Warnock et al. 1991; Hopwood et al. 1995). In the Verweij et al. (1995b) study, the LA test yielded positive results only during advanced stages of infection in most patients with suspected invasive aspergillosis and did not contribute to an early diagnosis. This study showed that an ELISA using a monoclonal antibody to GM detected GM in serum up to 5 days earlier than the LA test did. Although both LA and ELISA failed to detect one proven infection, the ELISA detected GM in two additional patients for whom the LA test continued to yield negative results. Moreover, GM was detected in more serum samples by ELISA than by LA. This suggests that monitoring sequential serum samples from high-risk patients during neutropenia may allow the diagnosis of invasive aspergillosis to be made at an earlier stage of infection. Furthermore, GM has been detected by ELISA in BAL fluid, but the antigen may appear sooner in serum (Verweij et al. 1995a). Galactofuran detection also has been described and may be an additional marker of invasive aspergillosis (Stynen et al. 1995).

One problem long associated with the increased sensitivity of immunoassays such as ELISA or LA has been the occurrence of false-positive results (Kurup and Kumar 1991; Warnock et al. 1991; Kappe and Schulze-Berg 1993). Therefore, to identify a genuine elevation of antigen level in serum, positive ELISA results should be found for at least two consecutive serum samples.

The studies by Verweij and colleagues (1995a, b, c) are encouraging and form the basis for a number of recommendations for the immunodiagnosis of invasive aspergillosis:

- antigen detection in serum at regular intervals by the double sandwich ELISA may allow the early diag-

nosis of invasive aspergillosis in immunocompromised patients
- twice-weekly collection and testing of serum samples from a patient during periods of neutropenia should be sufficient to detect an increase in the GM in serum early in the course of infection
- where there is a positive ELISA result, serum samples should be tested in order to exclude the possibility of a false-positive result
- confirmation of suspected invasive aspergillosis should be obtained by chest x-ray, computed tomography, or BAL.

Although antigen detection for the early diagnosis of invasive aspergillosis holds great promise for the future, determination of its full diagnostic potential awaits widespread availability and evaluation. In addition, greater effort has to be made in the search for immunodominant antigens.

Another approach to the diagnosis of aspergillosis that is independent of a host immunological response is the detection of fungal metabolites in the body fluids of patients. The presence of high levels of D-mannitol in the serum and tissues of experimentally infected animals has been shown to correlate with the presence and extent of invasive aspergillosis. Likewise, the presence of oxalic acid in BAL fluid has been proposed as a presumptive marker for aspergillosis.

Further information regarding the Platelia *Aspergillus* sandwich ELISA has been reported. Galactomannan has been detected by this test in BAL fluid specimens from patients with invasive aspergillosis and an excellent correlation has been found between serum and BAL fluid results (Verweij et al. 1995a). The detection of galactomannan in both BAL fluid and serum from a patient suspected of having invasive aspergillosis seems to provide strong evidence for the presence of this disease. The concentration of galactomannan in serum has been shown to correspond to the tissue burden of *Aspergillus* (Stynen et al. 1995), and there is some evidence that the course of the antigen titer is closely related to clinical outcome (Rohrlich et al. 1996; Verweij et al. 1997). Indeed, the amount of circulating galactomannan decreased in six of ten pediatric patients during antifungal treatment (Rohrlich et al. 1996) and in patients with invasive aspergillosis following bone marrow transplantation who responded to antifungal therapy (Patterson et al. 1995; Verweij et al. 1997).

Until now the sandwich-ELISA has been evaluated predominantly with serum samples from patients receiving treatment for hematological malignancies. The presence of a well-defined period of increased risk for invasive aspergillosis means that the sandwich ELISA can be used to screen patients at the time of risk of acquiring this infection. This approach may allow patients with invasive aspergillosis to be identified promptly and to benefit from early antifungal treatment.

The combination of antigen testing by ELISA and early CT scanning has been shown to improve diagnosis and outcome in immunocompromised patients (Caillot et al. 1997). Twenty-three histologically proven and 14 highly probable cases of invasive aspergillosis in 37 hematology patients were analyzed retrospectively. BAL fluid was positive in 22 (69 percent) of 32 cases. When BAL fluid was tested for antigen, the *Aspergillus* ELISA test was positive in 83 percent of cases. Starting from October 1991, early thoracic CT scans were routinely performed in febrile neutropenic patients with pulmonary infiltrates on chest radiograph. This approach allowed the investigators to recognize suggestive CT halo signs in 93 percent of patients, compared with 13 percent before this date. The mean time to a diagnosis of invasive pulmonary aspergillosis was reduced from 7 to 1.9 days.

The ELISA for detection of galactomannan becomes positive at an early stage of infection. Early detection is probably the most important feature of this assay, because the detection of antigenemia dictates the initiation of therapy. Recent studies, reviews, and recommendations highlight the usefulness of the galactomannan assay (Maertens et al. 1999, 2002; Denning 2000; Dupont et al. 2000). However, a number of important issues have to be addressed, for example false-negative reactivity, influence of host factors, and the degree of angioinvasion. Furthermore, some reports disagree with the consensus view (reviewed by Jones and McLintock 2003).

Other ELISA formats for the detection of *Aspergillus* antigen have been designed. Chumpitazi and colleagues developed an inhibition enzyme immunoassay (inhibition-EIA) to monitor for the occurrence of invasive aspergillosis in sera from 45 immunocompromised patients (Chumpitazi et al. 2000). The test used rabbit polyclonal antibodies and a mixture of components from *A. fumigatus*, containing three predominant antigens with molecular masses of 18 000, 33 000, and 56 000 Da. Circulating antigens were found in five of seven proven cases of invasive aspergillosis due to *A. fumigatus*. In two of the five positive cases, antigenemia was detected with inhibition-EIA earlier than with x-ray or other biological methods. No antigens were detected in the sera from two patients with proven invasive aspergillosis due to *A. flavus* and *A. terreus*, nor in the sera from four patients with probable invasive aspergillosis. Circulating antigens were not detected in the control group, composed of 30 healthy adult blood donors. Four of the 32 at-risk patients examined, although they displayed no definite evidence of invasive aspergillosis, gave a positive result in this test. The sensitivity, specificity, and positive predictive value of inhibition-EIA were 71.4, 94.4, and 71.2 percent, respectively. The data were compared with those obtained by an LA assay of galac-

tomannan that was positive in only one patient with probable invasive aspergillosis. The higher sensitivity obtained by inhibition-EIA may well be as a result of its ability to detect circulating antigens other than galactomannan in the sera of immunocompromised patients with invasive aspergillosis. It would be useful for the inhibition ELISA to be compared with the Platelia ELISA for galactomannan.

DETECTION OF *ASPERGILLUS* DNA BY POLYMERASE CHAIN REACTION (PCR)

The limitations of antibody detection and the problems of sensitivity associated with antigen detection have prompted the evaluation of the PCR for the diagnosis of invasive aspergillosis (Alexander 2002; Kawazu et al. 2003). The main advantages of PCR appear to be that it detects low burdens of fungal genetic material and warns of the presence of possible invasive aspergillosis. A number of PCR techniques have been developed to detect either individual species or general primer-mediated methods to detect filamentous fungi in general (Melchers et al. 1994; Montone and Litzky 1995). Various clinical specimens have been analyzed by these methods, including sputum, whole blood, and BAL fluid. Early reports described methods to amplify the gene for *A. fumigatus* 18 kDa ribonucleotoxin (Reddy et al. 1993). Subsequently, a PCR, based on universally conserved sequences within fungal large rDNA, including that of *A. fumigatus*, was described (Haynes et al. 1995). Primers to sequences of large subunit rDNA genes, which are universally conserved within the fungal kingdom, were capable of amplifying DNA from 43 strains representing 20 species (12 strains) of medically important fungi (Haynes et al. 1995). Sequence analysis of the products from *A. fumigatus* allowed the design of specific primers which only amplified homologous DNA. This approach allowed the detection and identification of *A. fumigatus* within 8 hours from simulated specimens.

The sensitivity of PCR is an important issue. The lower limit of detection reported for *A. fumigatus* corresponds to 10–100 c.f.u. per sample (Reddy et al. 1993; Spreadbury et al. 1993; Tang et al. 1993). Of equal concern is the question of false positives. In a competitive PCR assay applied to BAL samples, this problem was highlighted (Bretagne et al. 1995). Here a competitive, internal control was incorporated into a PCR designed for the detection of *Aspergillus* sp. DNA in BAL samples. For this purpose, a 1 kb mitochondrial DNA fragment of *A. fumigatus* was sequenced. The primers used allowed amplification of *A. fumigatus*, *A. flavus*, *A. terreus*, and *A. niger* DNAs, but not DNA of other fungi and yeasts. BAL samples from 55 consecutively enrolled patients were tested. Of 28 immunocompromised patients, six were PCR positive, three died of invasive pulmonary aspergillosis and their BAL cultures yielded *A. fumigatus*, and three were culture negative and did not develop invasive pulmonary aspergillosis. Of 15 HIV-positive patients and nine immunocompetent patients, five and four, respectively, were both PCR positive and culture negative, and none developed aspergillosis. Therefore, in this evaluation, PCR confirmed invasive pulmonary aspergillosis in three patients but gave positive results for 25 percent (12 of 49) of the patients who did not have evidence of aspergillosis. The authors conclude that the predictive value of PCR-positive results seems low for patients at risk for aspergillosis and that the risk of contamination of reaction buffers or biological samples with aspergillus conidia was high and was a major consideration if the potential diagnostic benefit of PCR was going to be realized.

There have been a number of reports on the use of PCR for the detection and identification of *Aspergillus* spp. Einsele and colleagues reported an oligonucleotide primer pair consisting of a consensus sequence for a variety of fungal pathogens, whilst the species-specific probes used for species identification were derived from a comparison of the sequences of the 18S rRNA genes of *Aspergillus* and *Candida* spp. (Einsele et al. 1997).

Verweij and coworkers sought to compare the sensitivity and utility of the double-sandwich ELISA for *Aspergillus* galactomannan with that of a PCR-based system in BAL fluid samples from 19 patients who were treated for hematological malignancies and suspected of having invasive pulmonary aspergillosis (Verweij et al. 1995a). ELISA was also performed with serum samples. All patients had fever and pulmonary infiltrates on the chest radiograph on the day that the BAL fluid was obtained. *Aspergillus* spp. were detected by PCR or ELISA in five of seven patients who had radiological evidence of invasive aspergillosis.

While most PCR systems for detection of aspergillosis use whole blood or BAL as a source, the possibility of using serum was investigated by Yamakami et al. (1996). Employing a nested PCR method, these investigators worked with two sets of oligonucleotide primers derived from the sequence of the variable regions V7–V9 of the 18S rRNA genes of *A. fumigatus*. The DNA fragment of interest was detected in the serum of mice with disseminated aspergillosis and in patients with invasive aspergillosis.

Walsh and colleagues reported the use of single-strand conformational polymorphism (SSCP) as a technique for detecting and delineating differences between fungal species and genera (Walsh et al. 1995). These investigators used a 197 bp fragment amplified from the 18S rRNA gene, which is common to all medically important fungi. After amplification, the fragments were denatured and run on an acrylamide-glycerol gel at room temperature or 4°C for 4.5 or 4 hours. The SSCP patterns of major and minor bands at room temperature permitted a distinction to be made between strains of *A. fumigatus* and *A. flavus*. The SSCP banding pattern among different strains of the same *Aspergillus* sp. was also consistent.

A variety of PCR protocols for human samples have been published, including PCR assays, methods detecting one species, members of a fungal family, or several species. As the incidence of fungal species in various infections is relatively low and identification of the infecting agent to the species level is required to guide appropriate treatment, the only efficient and economic approach may be a single protocol that is able to detect and identify many species. However, the protocols detecting several species use labor-intensive blotting protocols and sequential hybridizations with various radiolabeled probes for differentiation of species, which make these approaches impractical for routine laboratory use. In a recent study, a PCR method is described that is based on the sequence variation of the fungal ITS region (Hendolin et al. 2000). The method includes multiplex liquid hydridization with species-specific probes, and it employs nonradioactive and automated PCR product detection on a fluorescent automated DNA sequencer. Nonhybridized products are easily recognized on the sequencer and they can be used for identification by sequencing. The method has been applied to the analysis of tissue samples from a range of clinical specimens from deep sites. Total DNA was extracted from deep-tissue samples from 13 patients with suspected or proven fungal infection, and from nasal polyp tissue from seven patients with CRS. Broad-range primers were used to amplify the fungal ITS region (ITS 1-5.8S rRNA-ITS 2). Eight common fungal pathogens were identified by multiplex liquid hybridization with species-specific probes. The nonhybridized products were identified by sequencing either directly, or after segregation by cloning to allow assessment of mixed fungal populations. Twenty (95 percent) of 21 tissue specimens yielded PCR products, whereas culture resulted in only eight (38 percent) positive specimens. All culture or direct-microscopy positive specimens were PCR positive. Sequencing the nonhybridized PCR products identified an infecting agent in seven specimens, and sequences of unknown fungal origin were detected in three specimens. *Phoma glomerata* was detected by PCR in two CRS patients but culture was negative.

Another development has been the report of a two-step PCR assay that specifically amplifies a region of the 18S rRNA gene that is highly conserved in *Aspergillus* spp. (Skladny et al. 1999). A number of primers with the least homology to equivalent human or *Candida* gene sequences were screened for the pairs that gave the highest sensitivity and specificity. No crossreaction with numerous fungal and bacterial pathogens was observed. The assay allowed direct and rapid detection of down to 10 fg of *Aspergillus* DNA corresponding to 1–5 c.f.u./ml blood. A total of 315 blood and BAL samples from 140 subjects, including 93 patients at risk for invasive disease, were screened. The authors found 100 percent correlation between positive histology, culture, or high-resolution CT findings and PCR results. The test specificity was 89 percent. The method appears to be simple, specific, rapid, and inexpensive.

Other PCR formats have been adapted for the detection of *Aspergillus* DNA. A nested PCR test targeting the large ribosomal subunit genes of *Aspergillus* spp. was evaluated retrospectively on 175 serum samples from 37 bone marrow transplant recipients, 70 percent of whom received grafts from unrelated donors (Williamson et al. 2000). Six patients had proven infection, seven had probable infection, and three had possible infection, using the revised EORTC case definitions. These 16 patients were all PCR positive (57 out of 93 samples tested). Two additional patients who did not fulfill current diagnostic criteria, but in whom invasive aspergillosis was thought clinically probable, were also PCR positive (five of nine samples). Invasive aspergillosis was unlikely in the remaining 19 patients, four of whom were PCR positive on a single occasion (four of 70 samples). Three samples were inhibitory to PCR. The sensitivity of PCR in diagnosing patients with invasive aspergillosis was 100 percent, specificity was 79 percent, and positive predictive value was 80 percent, using the criterion of a single positive result. If two positive results were required, these values became 81 percent, 100 percent, and 100 percent, respectively. The median duration of infection documented by PCR was 36 days (range 3–248 days) in 17 of 18 patients (94 percent) who did not survive. Positive PCR results predated the institution of antifungal therapy in two-thirds of patients. Four patients became PCR positive during pretransplant conditioning therapy.

Many of these PCR formats are labor intensive and require a minimum of one working day to perform. The Light Cycler technique combines rapid in vitro amplification of DNA in glass capillaries with real-time species determination and quantification of DNA load. Loeffler and colleagues have established a quantitative PCR protocol for *A. fumigatus*, as well as for *C. albicans* (Loeffler et al. 2000). The sensitivity of the assay was comparable to those of previously described PCR protocols (5 c.f.u./ml). Specific detection of *A. fumigatus* could be achieved. The assay showed a high reproducibility of 96–99 percent. The assay was linear in a range between 10^1 and 10^4 aspergillus conidia. The Light Cycler allowed quantification of the fungal loads in clinical specimens from patients with hematological malignancies and histologically proven invasive fungal infections. In blood specimens spiked with aspergillus conidia, a sensitivity of 5 c.f.u./ml was demonstrated. All samples were also found to be PCR positive by PCR-ELISA analysis.

DETECTION OF CELL WALL β-1,3-D-GLUCAN

The cell wall of aspergillus hyphae, and the cell walls of other pathogenic fungi consist of mannans and glucans. The detection of circulating β-1,3-D-glucan is another

investigative strategy for diagnosis of invasive aspergillosis.

The plasma concentration of β-1,3-glucan has been measured at the time of routine cultures in febrile episodes (Obayashi et al. 1995). With a plasma cutoff value of 20 pg/ml, 37 of 41 episodes of proven fungal infections (confirmed at postmortem or by microbiological methods), including aspergillosis, were detected. All of the 59 episodes of nonfungal infections, tumor fever, or collagen-vascular diseases had concentrations below the cutoff value (specificity 100 percent). Of 102 episodes of fever of unknown origin, 26 had plasma glucan concentrations of more than 20 pg/ml. Of these, 102 cases are taken as nonfungal infections, the positive predictive value of the test was estimated as 59 (37 of 63), the negative predictive value as 97 percent (135 of 139), and the efficacy as 85 percent (172 of 202). Although a positive result does not indicate the specific cause of the detected fungal infection, this approach is very encouraging and warrants more extensive investigation in selected patient populations. More recent studies have confirmed the usefulness of this approach (Hossain et al. 1997). The test has now been reformatted as an ELISA (Glucatell – Associates of Cape Cod Inc.). Ostrosky-Zeichner and coworkers reported in an abstract from a multicenter trial evaluating the usefulness of the Glucatell assay as an aid to diagnosis of invasive fungal infections in humans (ICAAC 2003: www.iccac.org). The study evaluated the assay in 170 healthy controls and 163 patients with either proven or probable invasive fungal infections; the assay was able to provide a very high specificity and a high predictive value. This assay may be a useful diagnostic adjunct to cultures in the earlier diagnosis of invasive fungal infections.

CONCLUSIONS

Considering the differences in patient populations, conditions of specimen collection, and controls, no comparisons can be legitimately drawn between different antigen and PCR detection systems. The fact that these approaches have been found consistently to enhance the diagnosis of invasive aspergillosis is very encouraging. The recent approval of the Platelia *Aspergillus* galactomannan ELISA by the FDA in the United States should facilitate further understanding. A more comprehensive review of recent developments in the serological and immunological diagnosis of invasive aspergillosis is given by Yeo and Wong (2002), Jones and McLintock (2003), and McLintock and Jones (2004).

HISTOLOGICAL FEATURES

An extremely important characteristic of the histopathology of invasive aspergillosis is the striking tendency of the fungal hyphae to invade large and small arteries and veins, causing inflammation, thrombosis, and infarction. A variety of clinical manifestations and signs of organ dysfunction reflects this angiotropic behavior of *Aspergillus* spp. Aspergillus hyphae can be seen in thrombosed vessels and necrotic tissues, with regular septation and dichotomous branching at about 45°, advancing in the same direction. Aspergillus hyphae stain poorly with hematoxylin and eosin, and are best highlighted with Gomori's methenamine silver. A varying admixture of inflammatory cells is seen depending on the immune status of the patient.

Prognostic markers in aspergillosis

In allergic forms of aspergillosis, antibody titers may be of some prognostic value. It has been suggested that precipitins may decrease with successful corticosteroid therapy. IgE levels are, however, the most useful parameter to follow in the treatment of ABPA patients. The total IgE often rises before a clinical relapse, and the duration of therapy may be judged based on the fall in IgE level.

Tests for aspergillus precipitins are often helpful in the diagnosis of the different forms of aspergillosis that can occur in the noncompromised patient. Precipitins can be detected in up to 70 percent of patients with allergic aspergillosis and over 90 percent of patients with aspergillomas.

The precipitin test is also useful for the diagnosis of chronic necrotizing aspergillosis of the lung and other invasive forms of aspergillus infection, such as endocarditis, provided that the patient is not immunosuppressed.

The detection of precipitins in a neutropenic patient with unresponsive fever or a lung infiltrate is often sufficient to prompt the initiation of therapy, but it must be stressed that a positive test result is not proof of infection. Nor does a negative precipitin test result preclude the diagnosis of aspergillosis in an immunocompromised patient, because such individuals are often incapable of mounting a detectable serological response.

Tests for the detection of circulating aspergillus antigen in blood and urine offer an alternative means of diagnosing aspergillosis in the immunocompromised patient. Changing titers of galactomannan may predict treatment outcomes or indicate the progression of disease. However, aspergillus galactomannan is rapidly cleared from the circulation and frequent sampling is required for optimal detection of antigen.

Levels of antigenemia and antigenuria may correlate with the clinical course in invasive aspergillosis. Data in animal studies and some from patient series would suggest that antigen levels rise as the clinical condition worsens. Also, some studies have shown that efficacious antifungal therapy causes antigen levels to fall; however, this has not been confirmed in all studies. At this time, it is probably premature to derive any universal correlates for antigen levels in this disease.

In conclusion, rapid serological and molecular diagnostic methods facilitate the early diagnosis of invasive fungal infection and would appear to be most useful when used prospectively to screen high-risk patients. However, in order to determine the optimal approach to treatment it is essential that these tests are incorporated into management strategies and their impact on incidence of invasive fungal infection and clinical outcome evaluated in further clinical trials (Jones and McLintock 2003).

Future directions of diagnostic techniques

In the field of medical mycology, DNA-Chip technology appears to be the most promising molecular technique and has several potential applications, including:

- pathogen identification either of single species or part of a panel (as for example fungi causing fungemia)
- detection of antifungal resistance alleles
- virulence factors in bacteria; fungal typing in cases of nosocomial infection or for molecular epidemiologic purposes
- host–pathogen interaction with gene expression arrays.

It is likely that the panel strategy will be increasingly applied to the diagnosis of systemic fungal infections. Currently, most of the applications of DNA-Chip technology have been in the field of cancer, human genetics, or the monitoring of cellular gene expression. A DNA-Chip or DNA-Microarray is a small surface, usually glass or silica, which is covered by hundreds to hundreds of thousands of different oligonucleotides. Each oligonucleotide is represented on the Chip as millions of copies. These Chips are used in hybridization reactions to detect nucleic acids generated from a sample by an amplification technique. We are only at the beginning of the story of the use of DNA-Chips in the field of microbial diagnostics. Small microarrays have been used to identify bacteria in blood cultures using the 23S ribosomal gene. Very few fungal applications have been described. A DNA-Chip test requires approximately 6 hours to be performed. First DNA or RNA must be extracted from the sample using standard existing procedures. Amplification is then made with PCR, reverse transcriptase polymerase chain reaction (RT-PCR), or nucleic acid sequence based amplification (NASBA). The amplification products are cleaved to fragments of approximately bases and labelled with a fluorescent marker. The labelled products are then hybridized on the chip and the chip is thoroughly washed. Finally, using a confocal laser reader, the fluorescence, which is proportional to the amount of hybridized material on an individual oligonucleotide, is measured on each printed spot. One particular technique that is currently being evaluated for fungal diagnostics is arrayed primer extension (APEX). This is an integrated system with multiplex primer extension on a DNA array, fluorescence imaging, and data analysis. Fungal DNA is amplified by PCR, digested enzymatically, and annealed to the immobilized primers, which promote sites for template-dependent DNA polymerase extension reactions using four fluorescently labeled dideoxynucleotides. This and other methodologies will hopefully be developed into commercially available tests for the mycology laboratory.

MANAGEMENT

A number of new reviews and monographs have been published which should be consulted for detailed aspects and recommendations regarding the treatment of diseases caused by *Aspergillus* (Chiller and Stevens 2000; Stevens et al. 2000a; De Marie 2000; Judson and Stevens 2001; Reichenberger et al. 2002; Advances against aspergillosis 2003; Richardson and Jones 2003; Richardson and Warnock 2003; Anonymous 2004). Further information can be found on the *Aspergillus* website: www.aspergillus.man.ac.uk. A detailed account of the clinical pharmacology of all drugs currently used and those being developed for treating aspergillosis has been published by Groll et al. 1998b.

Allergic aspergillosis

Mild disease may not require treatment. Prednisone is the drug of choice because it is effective in reducing symptoms, improving chest x-rays, and clearing positive sputum cultures. The usual dosage regimen is 1.0 mg/kg/day until x-rays are clear, then 0.5 mg/kg/day for 2 weeks. The same dose is given at intervals of 48 hours for another 3–6 months, and then the dose is tapered off over another 3 months. The initial regimen should be resumed if the condition recurs. Bronchodilators and postural drainage may help to prevent mucus plugging. Treatment with antifungal drugs is not known to be helpful (Ikemoto 1992). However, more recent reports suggest that antifungal treatment may be helpful (Leon and Craig 1999; Salez et al. 1999; Chiu 2003; Stevens et al. 2000b, 2003).

Aspergilloma (fungus ball) of the lung

Surgical resection is indicated if massive or recurrent hemoptysis should occur. On occasion, segmental or wedge resection will suffice, but lobectomy is usually required to ensure complete eradication of the disease (Jewkes et al. 1983).

If surgical intervention is contraindicated, endobronchial instillation or percutaneous injection of amphotericin B may be helpful (Jewkes et al. 1983; Yamada et al. 1993). The optimum dosage has not been determined, but 10–20 mg amphotericin B in 10–20 ml distilled water

instilled two or three times per week for about 6 weeks has proved successful. Larger doses (40–50 mg) have been instilled into lung cavities using percutaneous catheters. Itraconazole does not appear to be effective (Campbell et al. 1991).

The treatment of mild-to-moderate bleeding and asymptomatic patients remains controversial, but observation without intervention may be the best approach to management. Recent reports suggest that antifungal treament may be useful in the management of aspergilloma (Kaestel et al. 1999; Ikemoto 2000; Kawamura et al. 2000; Regnard et al. 2000).

Chronic necrotizing aspergillosis of the lung

Treatment with an antifungal drug, such as amphotericin B, is often the first step in management, but surgical resection of necrotic lung and surrounding infiltrated tissue may also be required. The long-term prognosis is poor.

Infection of the paranasal sinuses

In some cases of paranasal aspergillus granuloma, surgical removal of infected material, with drainage and aeration, is curative. Often, however, the condition will recur, necessitating further surgical intervention. The long-term results are generally poor. Postoperative treatment with itraconazole appears promising as a means of preventing relapse. The drug should be given at a dosage of 200 mg/day for at least 6 weeks.

Neutropenic patients with acute aspergillus sinusitis require surgical débridement and treatment with amphotericin B (1.0 mg/kg/day).

Endophthalmitis

Patients with aspergillus endophthalmitis should be treated with intravenous amphotericin B (1.0 mg/kg/day). Surgical débridement and intravitreal instillation of amphotericin B (5 μg doses two or three times) may also be required.

Endocarditis

Aspergillus endocarditis requires aggressive medical and surgical treatment. Treatment with high-dose amphotericin B (1.0 mg/kg/day) alone is ineffective. Infected tissue and prostheses must be removed.

Osteomyelitis

Surgical débridement of necrotic tissue is important in the management of aspergillus osteomyelitis. Most patients with vertebral osteomyelitis undergo simple débridement as part of their initial diagnostic procedure. Later procedures include radical débridement with bone grafting. Both medical and surgical treatment are required if ribs are infected.

Treatment with itraconazole (400 mg/day) has proved successful in several patients with aspergillus osteomyelitis.

Cutaneous aspergillosis

High-dose amphotericin B (1 mg/kg/day) is the treatment of choice. Débridement of cutaneous lesions that arise at catheter insertion sites should be delayed until the neutrophil count has recovered.

Acute invasive aspergillosis

The successful management of acute invasive aspergillosis in the neutropenic patient depends on the prompt initiation of antifungal treatment (within 96 hours of the onset of infection) (Denning and Stevens 1990; Denning 1994a; Keating et al. 1994). The prognosis is poor if the neutrophil count does not recover.

The drug of choice for the treatment of disseminated aspergillosis is amphotericin B. There are numerous regimens for the administration of this drug, but there is widespread agreement that in neutropenic patients it is important to give the full dose of amphotericin B from the outset. High doses must be used (at least 1.0 mg/kg/day).

The optimum duration of treatment has not been established, but amphotericin B should be continued at least until the neutrophil count is more than 0.5×10^9/l. Thereafter treatment should be continued until symptoms resolve and relevant radiological abnormalities (on x-rays and CT scans) disappear. The shortcomings of current methods of diagnosis often require clinicians to proceed to amphotericin B treatment without waiting for formal proof that a neutropenic patient who has persistent fever (>72–96 hours duration), and is unresponsive to antibacterial drugs, has aspergillosis. Empirical treatment should be initiated with the usual test dose (1 mg) of amphotericin B. If possible, the full therapeutic dosage level should be reached within the first 24 hours of treatment (Fraser and Denning 1993).

Neutropenic patients who recover from aspergillosis may suffer from reactivation of the infection during subsequent periods of immunosuppression. One solution to this problem is to begin empirical treatment with amphotericin B (1 mg/kg/day) not less than 48 hours before antileukemic treatment is commenced. The drug should then be discontinued until the neutrophil count has recovered.

During the 1980s, several investigators incorporated amphotericin B into lipid vehicles and showed a reduction in the toxic adverse effects without loss in the effec-

tiveness of amphotericin B. Initially, such formulations were produced locally and used at single hospitals. In more recent years, lipid complexes of amphotericin B have become commercially available. These formulations include:

- the liposome AmBisome (Gilead Sciences, Foster City, CA, USA)
- a lipid vesicle – amphotericin B colloidal dispersion: Amphotec, Amphocil (InterMune, Brisbane, CA, USA)
- an amphotericin B–lipid complex: Abelcet (Enzon, Bridgewater, NJ, USA).

All of these preparations differ in size, structure, and pharmacokinetics, and, to a certain extent, in the clinical efficacy in the treatment of invasive aspergillosis (reviewed by Tollemar and Ringden 1995 and Barrett et al. 2003).

The treatment of invasive aspergillosis in bone marrow transplant patients has been reviewed recently by Marr et al. 2002; Richardson and Warnock 2003; Wiederhold et al. 2003, and treatment guidelines are published as *Therapeutic guidelines in systemic fungal infections* (Richardson and Jones 2003) and on Clinical Mycology Online (www.clinical-mycology.com).

AMBISOME (LIPOSOMAL AMPHOTERICIN B)

Liposomal amphotericin B (AmBisome) is well tolerated and doses as high as 3–5 mg/kg/day have been administered without significant side effects. Some 10 000 patients have been treated worldwide over the past 6 years. Administration of the drug in this form has sometimes eradicated aspergillus infection in neutropenic patients, and it should be considered in patients who have failed to respond to the conventional parenteral formulation, or who have developed side effects that would otherwise necessitate discontinuation of the drug.

A representative study highlighting the use of AmBisome in invasive aspergillosis is that by Mills et al. (1994). In a single-center study, the diagnosis of aspergillosis was proved in 21 of 116 patients with signs indicative of invasive aspergillosis (with four patients diagnosed postmortem). Of these 21 patients, 13 (62 percent) obtained complete or excellent partial resolution. Of the 17 patients with aspergillosis confirmed in life, the response was 77 percent (13 of 17). In eight patients, liposomal amphotericin B was discontinued when the neutrophil count was below 1×10^9/l, without recrudescence of the infection. Complete hematological remission was confirmed in nine responders on recovery from chemotherapy; three were found to have persistent disease and two had recurrent aspergillosis following subsequent chemotherapy. Of the eight nonresponders, four had refractory malignancy and four died before assessment was possible. In a further report, Ng and Denning (1995) detail the results from 34 centers in the UK of 17 cases of definite aspergillosis treated with AmBisome. The overall response rate was 59 percent (10 of 17). Mean (±SD) cumulative doses of AmBisome received by the responders and those who failed to respond were 2 081±1 189 mg and 1 207±839, respectively. Mean durations of treatment were 17±8 days and 7±4 days, respectively. All six patients who received therapy for more than 14 days responded, whereas 75 percent of those (three of four) who were treated for 5 days or less died. The average maximum daily dose received/tolerated by the group as a whole was 3±1 mg/kg/day (range 1–5 mg/kg/day).

AmBisome was used as 'salvage' therapy in seven patients who received conventional amphotericin B as first-line treatment but either failed to respond or developed renal insufficiency as a result of treatment. The response rate among this group of patients was 43 percent (three of seven). Of ten of those who did not receive prior therapy with conventional amphotericin B, eight (80 percent) responded to AmBisome therapy.

The data concerning the efficacy of AmBisome in the treatment of mycologically proven cases of invasive aspergillosis, in the analysis by Ng and Denning (1995) of compassionate use, are similar to those reviewed by Tollemar and Ringden (1995) (17 of 29 or 60 percent cure/improvement). This survey emphasizes the point that those patients who responded to AmBisome tended to have received a larger (cumulative) dose for a longer period of time than those in whom treatment failed. Among the patients who had proven invasive aspergillosis, those in whom AmBisome was used as salvage therapy had a less favorable prognosis than those who had never been treated with conventional amphotericin B. AmBisome (up to 5 mg/kg/day) was well tolerated in this study, even in one patient who had previously had a severe drug reaction after conventional amphotericin B therapy.

A notable feature of AmBisome is the very low incidence of acute infusion-related adverse reactions; in fact, where such reactions do occur patients appear to tolerate subsequent doses much more readily. There is no requirement for test dosing, slow escalation, or premedication.

A number of recent clinical evaluations and reviews have reinforced the earlier perception of AmBisome being a safe and effective treatment for invasive aspergillosis (Ribaud and Gluckman 1996; Coukell and Brogden 1998; Ringden et al. 1998). An illustrative study is that of Leenders and colleagues who reported a comparison between AmBisome 5 mg/kg/day with conventional amphotericin B 1 mg/kg/day (Leenders et al. 1998). Among patients with suspected or documented pulmonary aspergillosis, 11 (42 percent) patients on AmBisome and six (21 percent) patients on conventional amphotericin B had a complete response. Other trials have been reported by Andström et al. (1996) and Clark et al. (1998).

More recent information can be found in Marr et al. (2002) and Wiederhold et al. (2003). High-dose AmBisome has become an attractive therapeutic option for the management of invasive aspergillosis, although further studies are needed to assess this approach (Walsh et al. 2001; Martin et al. 2003).

AMPHOCIL/AMPHOTEC

Amphocil [amphotericin B colloidal dispersion (ABCD)] is formed from equimolar amounts of amphotericin B and cholesterol sulfate; it has a disk-like form with a mean size of 122 nm and is rapidly taken up by the liver. Despite the lack of published studies, ABCD has been used in a number of centers and the data presented in abstract form (Oppenheim et al. 1995). The effectiveness of ABCD has been studied in a number of animal models of infection. In a rabbit model of invasive aspergillosis, conventional amphotericin B, at a dosage of 1.5–4.5 mg/kg/day, was more effective in eradicating hepatic and renal infection than ABCD at dosages from 1.5 to 4.5 mg/kg/day (reviewed by Warnock 1995). Infection persisted in the lungs even when animals were treated with a lethal 4.5 mg/kg dose of conventional amphotericin B. However, ABCD could be administered at a much higher dosage (15 mg/kg/day) and this eradicated the infection. In a second report involving a rabbit model of invasive aspergillosis (reviewed by Warnock 1995), animals treated with ABCD had better survival rates (33 percent and 70 percent at dosages of 1 and 5 mg/kg/day) than those treated with conventional amphotericin B (14 percent at 1 mg/kg/day).

The clinical data are still too limited to allow firm conclusions to be drawn, but published information on the compassionate use of ABCD in patients with invasive aspergillosis compares favorably with that for conventional amphotericin B, but not with AmBisome. The collective global experience has been reviewed by Barrett et al. (2003). Of patients at 45 centers, 168 were entered into an open-label, non-comparative evaluation of the efficacy and safety of ABCD in confirmed systemic mycoses. To be included in the study, patients had either to have a systemic fungal infection that had failed to respond to conventional amphotericin B or to be unsuitable for conventional amphotericin B because of nephrotoxicity from conventional amphotericin B or other drugs or because of preexisting renal impairment. A total of 97 patients were evaluable for clinical efficacy of whom 33 percent had invasive aspergillosis. Thirty-four per cent of cases of aspergillosis responded. In a separate analysis of 21 patients with proven fungal infections treated with Amphocil in two UK hospitals, a clinical response was seen in eight of 13 patients with aspergillosis.

Further US experience is reported by White et al. (1997). Eighty-two patients with proven or probable aspergillosis who were treated with Amphocil were compared retrospectively with 261 patients with aspergillosis who were treated with conventional amphotericin B. Response rates (48.8 percent) and survival rates (50 percent) among Amphocil-treated patients were higher than those (23.4 percent and 28.4 percent, respectively) among amphotericin B-treated patients. This study suggested also that in the treatment of aspergillosis, Amphocil caused fewer nephrotoxic effects than conventional amphotericin B and that the efficacy of Amphocil was at least comparable with that of amphotericin B.

More recent information about the use of Amphocil in aspergillosis can be found in Noskin et al. 1999, Roland 1999, and Barrett et al., 2003.

ABELCET

Abelcet [amphotericin B lipid complex (ABLC)] consists of amphotericin B complexed with two lipids, dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol, in a 1:1 drug:lipid molar ratio. In animal models, ABLC has been shown to be at least as effective as amphotericin B and substantially less toxic.

Two key studies represent the current clinical experience with ABLC. As part of a 225 patient study where ABLC was used at 5.0 mg/kg/day, complete response or improvement was achieved in 60 percent (43 of 72) of aspergillosis cases (reviewed by Barrett et al. 2003). Among the different patterns of invasive aspergillosis, the response rate was greatest for sinus aspergillosis (83 percent), followed by pulmonary aspergillosis (58 percent) and extrapulmonary aspergillosis (52 percent). Extrapulmonary aspergillosis included single-organ infection (n=14) and disseminated infection (n=13). The response to ABLC in single-organ extrapulmonary aspergillosis showed a trend towards a more favorable response in nine of 14 cases (64 percent) versus five of 13 (38 percent) in disseminated aspergillosis. There was also a trend towards a more favorable response in all nondisseminated aspergillosis (38 of 59 or 64 percent) versus disseminated aspergillosis cases (five of 13 or 38 percent). The authors note that responses were obtained in patients with disseminated aspergillosis unresponsive to or intolerant of conventional amphotericin B, and that this response was encouraging considering that the mortality rate in this disease approaches 100 percent.

The second major study of the use of ABLC in aspergillosis is where the efficacy, nephrotoxicity, and mortality of patients with invasive aspergillosis treated with ABLC (5 mg/kg/day) in an emergency program were compared with those of a historical control group of patients treated with conventional amphotericin B (reviewed by Barrett et al. 2003). The patients selected (n=151) were those who had failed to respond to antifungal therapy, and had nephrotoxicity or preexisting renal insufficiency. The historical control patients (n=122) had received 500 mg or more of conventional

amphotericin B or had nephrotoxicity. All patients met the definitions for definite or probable aspergillosis. A distinction between the different disease patterns of aspergillosis is not made. ABLC-treated patients showed greater probability of survival (P=0.0233) (median of 52 versus 31 days) and higher response rates (40 percent versus 23 percent, P=0.002) than patients treated with conventional amphotericin B. Among patients with serum creatinine of 221 μmol/l or more when ABLC treatment began, a significant decrease from baseline levels was observed between week 2 and week 5 (P=0.004). The authors conclude from this study that ABLC appears to be associated with at least equal, and possibly better, efficacy and clearly less toxicity compared with conventional amphotericin B in the treatment of disseminated aspergillosis.

Data on ABLC are limited, although the formulation seems to have an acute toxicity profile (pyrexia, chills) very similar to that of amphotericin B. As clinical experience with this drug is restricted to a few centers, it will be some time before more definitive statements can be made regarding overall toxicity.

A number of studies have confirmed the usefulness of ABLC in the treatment of severe invasive candidosis and as second-line treatment of invasive aspergillosis, cryptococcosis in HIV patients, and miscellaneous fungal infections (Oravcova et al. 1995; Franklin et al. 1997; Mehta et al. 1997). The drug appears to be cleared rapidly from the serum. High tissue levels, especially in the lung, have been recorded in animals, followed by rapid clearance of the drug from the lung area over 24 hours. Human data regarding accumulation of ABLC in lung tissue appears to be based on postmortem tissue from one patient. The initial clinical trials were conducted in the USA (reviewed by Lister 1996). The size and quality of these studies varied considerably and the conclusions that can be drawn are limited in the absence of confirmatory studies.

The recommended dosage of ABLC is 5 mg/kg and this should be infused over a period of 2 hours for at least 2 weeks. Response to treatment times is highly variable. This formulation of amphotericin B has been administered to individual patients for up to 11 months, to a cumulative dosage of 50 g without significant toxic side effects.

Very few studies evaluating the effectiveness of ABLC in invasive aspergillosis have been described. Mehta et al. (1997) report that five of seven evaluable patients with aspergillus pneumonia responded to ABLC (daily dose of 5 mg/kg).

A further study regarding the safety and efficacy of ABLC has recently been reported by Walsh et al. (1998). ABLC was evaluated in 556 cases of invasive fungal infection treated through an open-label, single-patient, emergency-use study of patients who were refractory to or intolerant of conventional antifungal therapy. This large clinical trial demonstrated a significant improvement in renal function following the initiation of therapy with ABLC, particularly in patients with amphotericin B-induced nephrotoxicity or primary renal dysfunction. Among the 291 mycologically confirmed cases evaluable for therapeutic response, there was a complete or partial response to ABLC in 55 of 130 cases of aspergillosis. Among the different patterns of invasive aspergillosis, the response rate was greatest for single-organ extrapulmonary aspergillosis and for sinus aspergillosis, followed by pulmonary and disseminated aspergillosis.

As clinical experience with this drug is restricted to a few centers, it will be some time before more definitive statements can be made regarding overall efficacy and toxicity.

There is some concern regarding the incidence and severity of toxicity of ABLC. Ringden et al. (1998) reported their experience with ABLC for proven or suspected invasive fungal infection in 19 patients with a variety of hematological conditions. ABLC was discontinued in 14 of the 19 patients due to side effects. These included renal insufficiency, increase in bilirubin, erythema, increased alanine aminotransferase (ALAT), fever and chills, severe vomiting, and a variety of other drug-related effects. The authors express the opinion that ABLC is far more toxic than AmBisome. In their experience, AmBisome was discontinued in only six of one series of 187 patients. However, it is pointed out that the dose of AmBisome used was much lower in most patients.

Further experience with Abelcet is reported by Boyle and Swenson (1999), Linden et al. (1999), Martino et al. (1999a, b), Walsh et al. (1999b), and reviewed by Barrett et al. (2003).

ITRACONAZOLE

Itraconazole is comparable in vitro to amphotericin B in efficacy. Itraconazole capsules are tolerated with an acceptable level of toxicity. Treatment with itraconazole (400 mg/day) has sometimes proved successful in neutropenic individuals with invasive aspergillus infection (Jennings and Hardin 1993). However, absorption of the drug from the gastrointestinal tract can be a problem and blood concentrations must be measured at regular intervals. Recently, there have been several reports on the successful treatment of invasive pulmonary aspergillosis in neutropenic patients (reviewed by Beyer et al. 1994a; Denning et al. 1994). The accumulated data on itraconazole are highlighted by a small randomized trial where itraconazole (capsules) 400 mg/day was compared with amphotericin B at a dose of 0.6 mg/kg/day in 32 patients with suspected or proven fungal infection (reviewed by Beyer et al. 1994b). Invasive pulmonary aspergillosis was suspected or documented in 13 of 32 (41 percent) of the patients. The overall response rate was similar, with 63 percent in the itraconazole arm and

56 percent in the amphotericin B arm, but all three fatalities with documented invasive pulmonary aspergillosis were treated with amphotericin B. Patients with candida infections responded better to amphotericin B, whereas patients with aspergillus infections had a better response to itraconazole, although the response was not significant. The median treatment duration of 20 days with itraconazole and 13 days with amphotericin B was short, and the responses to conventional amphotericin B and itraconazole were associated with neutrophil recovery in most patients. Itraconazole has also been successfully used in the treatment of invasive pulmonary aspergillosis in patients who did not respond to amphotericin B (see Beyer et al. 1994b). The use of oral itraconazole plus intranasal amphotericin B for prophylaxis of invasive aspergillosis has been described (Todeschini et al. 1993).

More recent studies reaffirm the value of itraconazole in the treatment of invasive aspergillosis, especially where an early diagnosis is achieved. An illustrative study is that of Caillot et al. (1997) where systematic use of CT added to the early diagnosis of invasive aspergillosis. Twenty-six of 37 patients with proven or highly probable invasive aspergillosis were improved or cured by antifungal treatment. Twenty-two patients received itraconazole (median dose 400 mg/day) for a median length of 302 days (range 103–1 185). No severe adverse reactions were seen. The plasma levels of itraconazole were determined in 16 patients, and in 14 of them the residual levels of itraconazole were greater than 0.6 μg/ml during the first 20 days of treatment. In 13 cases, amphotericin B (median dose 1.3 mg/kg/day) was combined with itraconazole for a median duration of 9 days (range 5–20).

There is limited experience with the new oral solution formulation of itraconazole as first-line treatment of invasive aspergillosis – 400–600 mg/day for 4 days then 200 mg twice daily. An alternative approach appears to be the use of high-dose itraconazole solution (400–600 mg) following 7–14 days of AmBisome.

An intravenous formulation of itraconazole is currently being evaluated and has been licensed in the UK, the USA, and The Netherlands. Data are available only in abstract form at the moment. Further studies are being conducted to determine the efficacy of this formulation in the treatment of aspergillosis and as empirical therapy for fever of unknown origin. The current dosing schedule of the intravenous formulation is as follows:

- Day 1 and 2: 1-hour infusion 200 mg twice daily
- From day 3 onwards: a single 1-hour infusion 200 mg each day. Safety of use for periods longer than 14 days has not been established.

Recent reports on all formulations of itraconazole include: Popp et al. (1999); Prentice et al. (1999); Persat et al. (2000); Caillot (2003). Additional information and guidelines can be found on the *Aspergillus* website (www.aspergillus.man.ac.uk), and in *Therapeutic guidelines in systemic fungal infection* (Richardson and Jones 2003). Recent findings on itraconazole are found in a *Journal of Antimicrobial Chemotherapy* supplement (in press).

VORICONAZOLE

A new azole antifungal, voriconazole (Pfizer), formulated in both oral and intravenous forms, is currently being evaluated in clinical studies. It exhibits potent antifungal activity against clinical isolates of *Aspergillus* spp. in vitro. It appears to be more active in vitro compared to amphotericin B (Clancy and Nguyen 1998). For *A. fumigatus* the minimum inhibitory concentration (MIC) has been shown to be in the range 0.03–0.5 μg/ml and the MIC_{90} to be 0.25 μg/ml. In experimental aspergillosis in mice, oral voriconazole 30 mg/kg body weight per day appears to significantly delay or prevent mortality (Murphy et al. 1997). A number of clinical evaluations have demonstrated the effectiveness of voriconazole in invasive aspergillosis (initial clinical experience reviewed by De Pauw and Meis 1998). Caillot et al. (1997) described three patients who were cured and one who improved with voriconazole treatment (median dose 6 mg/kg/day; median duration 63 days). One patient failed to respond to a 26-day treatment course with voriconazole.

Further animal data have been reported by Chandrasekar et al. (2000). Their work compared the efficacies of amphotericin B and voriconazole against pulmonary aspergillosis in a guinea pig model. Voriconazole-treated animals had significantly better survival rates and a decreased fungal burden in the lungs compared with controls. Although no statistical difference was seen between the efficacies of voriconazole and amphotericin B, a trend favoring voriconazole was noted.

Currently, voriconazole is licensed for the treatment of patients aged 2 years or over with invasive aspergillosis. It may be administered either by mouth or intravenously, depending on the condition of the patient. It also appears to be active against other filamentous fungi besides *Aspergillus* (Perfect et al. 2003).

A review of the clinical efficacy of voriconazole in invasive aspergillosis can be found in Muijsers et al. (2002), and the *Drugs and Therapeutic Bulletin* (Anonymous 2004). The conclusion is that voriconazole appears to be a reasonable choice as a second-line therapy, not least because it offers the potential for intravenous or oral treatment of a broad spectrum of fungal infections, in both adults and children. However, there is no convincing published evidence to justify the claim that voriconazole is superior to amphotericin B at increasing survival rates in patients with invasive aspergillosis (Anonymous 2004).

CASPOFUNGIN

Caspofungin is a synthetic lipopeptide. As one of the echinocandins it inhibits the synthesis of β-1,3-D-glucan, an essential component of fungal but not mammalian cells. Its range of activity is restricted to *Aspergillus* and *Candida* spp. Caspofungin is licensed for the treatment of invasive aspergillosis in adults who have failed to tolerate or respond to conventional or lipid formulations of amphotericin B and/or itraconazole, and for the treatment of candidosis in non-neutropenic adults.

Published evidence on the efficacy of caspofungin in invasive aspergillosis is limited to an uncontrolled retrospective study, published only in abstract form (Maertens et al. 2002). This involved 83 patients with presumed invasive aspergillosis who had either failed to tolerate or not responded to unspecified antifungal therapy, and were given intravenous caspofungin for up to 162 days. A favorable response (i.e. resolution of, or improvement in, attributable clinical and radiological or bronchoscopic features) was reported in 45 percent of patients.

In conclusion, caspofungin appears to be better tolerated than conventional amphotericin B but there is little published evidence to justify its use in invasive aspergillosis (Anonymous 2004).

IN VIVO EFFECTS OF COLONY-STIMULATING FACTORS ON NEUTROPHIL FUNCTION AND INVASIVE ASPERGILLOSIS

The assessment of the effects of colony-stimulating factors on neutrophil function is contradictory, largely because of the diversity of methods used and the growth phase of the organism used. In vitro, granulocyte colony-stimulating factor (G-CSF) appears to be a weaker stimulus to the neutrophil metabolic burst than GM-CSF, tumor necrosis factor (TNF), or various interleukins (IL). Phagocytosis and fungicidal activity appear to be enhanced by exposure of normal effector cells to G-CSF, GM-CSF, or IL-8 (Roildes et al. 1993b, c; Richardson and Patel 1995). Pre-exposure to concentrations of IL-8 achievable in vivo significantly enhances phagocytic ingestion of *A. fumigatus* conidia (Richardson and Patel 1995). Furthermore, IL-8-primed neutrophils showed enhanced phagocytic activity to the chemotactic peptide *N*-formyl-methionyl-leucyl-phenylalanine.

CLINICAL TRIALS OF COLONY-STIMULATING FACTORS IN INVASIVE ASPERGILLOSIS

Closely paralleling preclinical trials in experimental infections, a number of studies have shown that macrophage colony-stimulating factor (M-CSF), G-CSF, and GM-CSF can reduce the severity and duration of chemotherapy-induced neutropenia; these growth factors are a useful adjunct to antifungal therapy (Spielberger et al. 1993). Undoubtedly, there will soon be other investigations of the benefits and risks of using colony-stimulating factors to enhance neutrophil production and upregulate their function. Furthermore, it is anticipated that this will produce a rapid growth in our understanding of the role of neutrophils in response to invasive aspergillosis. A limited number of studies have demonstrated the safe concomitant use of amphotericin B, granulocyte transfusions, and GM-CSF. Concern has been raised about the use of GM-CSF during serious fungal infection because this cytokine can inhibit neutrophil migration into the inflammatory zone measured in a standardized skin chamber assay.

The use of cytokines, together with standard and new formulations of amphotericin B, should be considered for granulocytopenic patients with such invasive fungal infections as invasive aspergillosis, particularly when there has been no response to antifungal therapy alone, and when bone marrow recovery is not expected for at least 10–14 days (Iwen et al. 1993). In a series of cases reported by Bodey et al. (1993), there were two patients with aspergillosis who were treated with GM-CSF and amphotericin B. A patient with underlying breast cancer, who had received a bone marrow transplant, contracted an aspergillus pneumonia. This patient only partially responded. A second patient with acute myeloid leukemia and *A. flavus* sinopulmonary infection failed to respond to combination treatment. The dose range of GM-CSF used in this series was 100–759 $\mu g/m^2$/day, based on initial phase 1 trials. This was considered to be too high because a number of patients developed capillary leak syndrome. It is advocated that doses in the range 15–30 $\mu g/m^2$ be used in future trials. However, cytokines should be used cautiously in the setting of persistent acute myeloid leukemia because the issues surrounding such treatment remain unresolved at the present time.

EMPIRICAL TREATMENT OF PRESUMED INFECTION

Persistent fever suggests an occult fungal infection. The likelihood of this increases with the number of preceding febrile episodes. It has been shown that 44 percent of patients suffering their fourth bout of fever had a fungal infection as the cause.

Patients with prolonged neutropenia (more than 7–10 days) or receiving high doses of glucocorticoids during neutropenia, and a high probability of invasive aspergillosis should be given empirical systemic antifungal therapy. This recommendation is based on numerous reviews and clinical studies. Such patients, with fever persisting despite antibiotic therapy or presenting at the onset of a febrile episode with findings suggesting the possibility of an invasive infection, should be started on antifungals. In this situation amphotericin B must be used. If possible, the full therapeutic dosage level (1.0–1.5 mg/kg/day of the conventional formulation) should be reached within the first 24 hours of treatment. There

is no need for gradual escalation of dosage, nor is there evidence to support the clinical prejudice that a lower dose can be used in suspected invasive disease.

Should the conventional formulation be contraindicated, one of the lipid-complexed formulations should be used instead. For example, in a Europe-wide randomized, double-blind comparative trial of the liposomal formulation of amphotericin B (AmBisome) versus conventional amphotericin B in the empirical treatment of both pediatric and adult febrile neutropenic patients, AmBisome (3 mg/kg/day) was as effective as conventional amphotericin B in the prevention of proven treatment-emergent fungal infections (Prentice et al. 1997). Of significance was the reduction in overall drug-related toxicity by two- to sixfold in patients treated with AmBisome compared with conventional amphotericin B. Severe drug-related adverse reactions were almost absent in patients treated with AmBisome. Nephrotoxicity, in patients not receiving concomitant nephrotoxic agents, was seen only in 3 percent of patients treated with AmBisome, compared with 23 percent of patients on conventional amphotericin B. Time to develop nephrotoxicity was longer in patients on AmBisome compared with conventional amphotericin B.

A significantly larger study, which formed the basis of a successful new drug application to the Federal Drug Administration (FDA) for the use of AmBisome in empirical therapy of presumed fungal infections in febrile, neutropenic patients has been reported (Walsh et al. 1999a). This study was a multicenter, double-blind trial that compared AmBisome (3 mg/kg/day) with conventional amphotericin B (0.6 mg/kg/day). Nearly 700 adult and pediatric patients with neutropenia and pyrexia of unknown origin (PUO) were randomized to receive either conventional amphotericin B or AmBisome. Therapeutic success, measured by a combination of factors including resolution of fever, absence of emergent fungal infection, and patient survival for at least 7 days after therapy, was equivalent between the two groups. There were significantly fewer proven treatment-emergent fungal infections in patients treated with AmBisome than in patients treated with conventional amphotericin B. Similar to the Prentice et al. (1997) report, there was a significant reduction in the frequency of infusion-related fever and in the development of nephrotoxicity. The conclusions that can be drawn from the Walsh et al. (1999a) study are that AmBisome was equivalent to conventional amphotericin B for empirical antifungal therapy in neutropenic patients, but superior in reducing proven treatment-emergent fungal infections, nephrotoxicity, and infusion-related toxicity.

The duration of treatment will differ from patient to patient. If the patient responds and a diagnosis of fungal infection is established, a full course of treatment should be given. More often, however, the patient responds and/or the neutrophil count recovers, but a firm diagnosis is not obtained. In this situation it is reasonable to discontinue amphotericin B when the neutrophil count goes above 1×10^9/l, the fever and other symptoms and signs resolve, and relevant radiological abnormalities return to normal.

Neutropenic patients who recover from invasive aspergillosis may suffer from reactivation of the infection during subsequent periods of immunosuppression. One solution to this problem is to begin empirical treatment with amphotericin B (1 mg/kg/day) not less than 48 hours before antileukemic treatment is commenced. This drug should be continued until the neutrophil count has recovered.

It is important to remember that empirical antifungal therapy does not preclude further investigation for other occult causes of fever (drug-induced fever, viral infection, possibly *Pneumocystis*, rarely parasites or mycobacteria). In addition, a change in fever pattern, including abatement of previously continuous fevers, which frequently follows initiation of amphotericin B therapy, cannot be taken as a guarantee of a favorable response to empirical antifungal therapy. Furthermore, efforts to document fungal infection during empirical therapy in order to adapt antifungal therapy to specific agents and their clinical symptoms should not be abandoned.

Recent reports, reviews, and guidelines regarding empirical treatment of fever in neutropenia include: Hamacher et al. (1999); Roland (1999); Wingard et al. (1999); Prentice et al. (2000); Marr (2002); Richardson and Jones (2003).

A recent review of voriconazole and caspofungin in the *Drugs and Therapeutics Bulletin* (Anonymous 2004) recommends that neither caspofungin nor voriconazole be used for empirical treatment of fever in patients with neutropenia.

TREATMENT OF INVASIVE ASPERGILLOSIS IN NEONATES

High dose (1.0–1.5 mg/kg/day) amphotericin B remains the cornerstone of treatment for both suspected and proven invasive aspergillosis. In neonates, the pharmacokinetics of amphotericin B are characterized by extreme variability between individuals and a comparatively lower clearance rate. However, no correlations between plasma concentrations and pharmacological effects have ever been established, and there is no evidence that these pharmacokinetic characteristics result in any clinical consequences. Indeed, several case series indicate that amphotericin B is usually tolerated without nephrotoxicity at daily doses of up to 1 mg/kg/day, even in very low-birthweight infants, and daily dosages of up to 1.5 mg/kg have been safely administered. It is recommended that a starting dosage of at least 1 mg/kg daily be used, in view of the high mortality associated with invasive aspergillosis. Because it has the potential to cause cardiac arrhythmias, amphotericin B should be

infused under careful monitoring, in particular in the presence of hyperkalemia and/or renal impairment.

Liposomal amphotericin B (AmBisome) has been tolerated at dosages of up to 5 mg/kg/day in more than 50 term and preterm infants (Groll et al. 1998b; Scarcella et al. 1998; Weitkamp et al. 1998). Published data regarding the efficacy of either Abelcet or Amphocil are lacking. The collective opinion is that AmBisome should be the salvage agent of choice in neonates refractory to or intolerant of conventional amphotericin B. A starting dose of 5 mg/kg/day is recommended for proven infections, with dosage adjustment only to limit toxicity (Groll et al. 1998b). Where there is fever of unknown origin without conclusive evidence of invasive aspergillosis, then empirical/pre-emptive AmBisome should be given at a rate of 3 mg/kg/day.

Itraconazole as the oral solution may be indicated in a stable patient with residual lesions. The drug is absorbed by preterm neonates. The recent licensing of intravenous itraconazole offers the opportunity to treat the condition parenterally.

COMBINATION THERAPY

Published data on the use of the new antifungals caspofungin or voriconazole in combination with other antifungal drugs is limited to case reports or case series. Further investigation of the efficacy and safety of caspofungin and voriconazole in combination therapy is needed (for recent reviews see: Lewis and Kontoyiannis 2001; Antoniadou and Kontoyiannis 2003; Steinbach et al. 2003).

PROPHYLAXIS

Old and new approaches to prophylaxis include aerosolized amphotericin B, low-dose intravenous amphotericin B, liposomal amphotericin B, and oral itraconazole (for general reviews see Prentice et al. 2000; Singh 2000; Cornely et al. 2003; Richardson and Warnock 2003). Guidelines can be found in Richardson and Jones (2003).

Amphotericin B inhalation

Aerosolized amphotericin B appeared to be promising in some of the early clinical trials, which have included patients undergoing bone marrow transplantation, and the incidence of aspergillus infections in some series dramatically decreased (compared with historical controls) (Jorgensen et al. 1989; Connealy et al. 1990; Jeffery et al. 1991; Myers et al. 1992; Beyer et al. 1993, 1994a, b). Unfortunately, these results have not been confirmed. A more recent study shows that, in contrast, aerosolized amphotericin B was poorly tolerated (Erjavec et al. 1997). Here, the value of inhaled amphotericin B against invasive pulmonary aspergillosis was evaluated in 61 neutropenic episodes in 42 patients treated for a hematological malignancy. Each patient was assigned to receive amphotericin B in doses escalating to 10 mg thrice daily but only 20 (48 percent) patients managed to complete the schedule regimen. One patient tolerated the full dose initially, but had to discontinue treatment when dyspnea developed as a result of pneumonia and acute respiratory distress. Another 22 patients (52 percent) experienced side effects, including eight (19 percent) who reported mild coughing and dyspnea but who tolerated the full dose, and three (7 percent) patients whose dose was reduced to 5 mg thrice daily. Another six (14 percent) patients could tolerate only 5 mg thrice daily, and five (12 percent) others stopped treatment because of intolerance. The study indicated that elderly patients and those with a history of chronic pulmonary obstructive disease were more likely to develop side effects during inhalation. Twelve (28 percent) patients developed proven or possible invasive fungal infection but no correlation was established between infection and the total amount of amphotericin B inhaled. The investigators concluded that prophylaxis with inhaled amphotericin B does not appear useful in preventing invasive pulmonary aspergillosis in neutropenic patients and is tolerated poorly. The type of nebulizer would appear to be a key issue in the delivery of amphotericin B aerosols throughout the respiratory tract. Many types of nebulizers exist. The nebulizer used by Erjavec and colleagues was capable of producing particles of 0.5–5.5 μm, sufficiently small to reach most components of the respiratory tree including the terminal bronchioles and alveolar sacs. However, nothing is known regarding the level of amphotericin B that is achieved in the pneumocytes of the alveolar epithelium that lines the alveolar ducts and sacs.

The question of safety and tolerance of inhaled amphotericin B has been investigated as part of a study to evaluate the benefit of aerosolized amphotericin B as prophylaxis against invasive aspergillosis (Dubois et al. 1995). The investigators looked specifically at oxygen saturation levels, peak flow values, and symptoms of patients given amphotericin B. Data are presented on a series of 18 patients and 132 amphotericin B administrations. Four (22 percent) of the patients stopped treatments because of nausea and vomiting which were believed to be due to the inhaled amphotericin B. For the remaining patients, no treatment was stopped because of symptoms or physiological changes caused by amphotericin B, although there were nine instances of clinically significant bronchospasm as defined by a drop in peak flow of 20 percent or more, nine clinically relevant increases in cough, and three clinically relevant increases in dyspnea. The findings from this study led the authors to draw the following conclusions. First, most prophylactic amphotericin B was well tolerated and did not cause any clinically or physiologically significant changes. Second, inhaled amphotericin B might in

some cases cause nausea and vomiting, which would lead to discontinuation of therapy. Third, asthmatic subjects are more likely to experience significant drops in peak flow values. The authors advocate that peak flow should be monitored and bronchodilators should be used prior to amphotericin B inhalation for known asthmatic subjects. Fourth, an occasional patient with no known history of asthma will consistently experience adverse symptoms with amphotericin B inhalation. It is clear from this study that whilst side effects do occur, neither the frequency nor severity of reactions appears to preclude the use of inhaled amphotericin B in the majority of patients. However, the specific benefit as prophylaxis against pulmonary aspergillosis has still to be resolved. It is possible that nebulized liposomal amphotericin B (AmBisome) may provide greater protection. In terms of drug levels in alveolar sacs and lung tissue of mice, aerosolization and delivery of liposomal amphotericin B was shown to be far superior to that of conventional amphotericin B and that liposomal amphotericin B was more effective than conventional amphotericin B when given as a prophylactic aerosol in clearing mouse lungs of *Aspergillus*, although this was very much inoculum concentration dependent (Allen et al. 1994).

Oral itraconazole prophylaxis (see below) combined with intranasal amphotericin B is another approach (Todeschini et al. 1993). Here, itraconazole capsules (200 mg/day) combined with intranasal amphotericin B (10 mg/day) was prescribed as prophylaxis in 164 patients. The incidence of proven aspergillosis was lower, as was the mortality rate. However, more experience is needed before this drug combination can be recommended for daily clinical practice, especially as the oral solution formulation of itraconazole will undoubtedly supersede the capsule form for routine prophylaxis.

Low-dose amphotericin B

The value of low-dose amphotericin B (0.15–0.25 mg/kg/day) as prophylaxis against *Aspergillus* spp. in patients undergoing allogeneic bone marrow transplantation has been explored in a number of studies (Rousey et al. 1991; Perfect et al. 1992). The data do not suggest a benefit compared with historical controls. For example, in a placebo-controlled prospective study involving 188 patients who underwent autologous bone marrow transplantation, amphotericin B (0.1 mg/kg daily) did not prevent aspergillus infection compared to the placebo group. One aspergillus infection was documented in each group. Prophylaxis was discontinued once an individual developed a persistent fever for 5 days despite treatment with broad-spectrum antibiotics. Suspected fungal infections were treated empirically with amphotericin B 0.6 mg/kg/day. In this study amphotericin B at 0.1 mg/kg/day did not prevent the emergence of aspergillosis compared with placebo.

The conclusions drawn from these earlier studies of the benefit of low-dose amphotericin B as prophylaxis against invasive aspergillosis are not clear. Overall, low-dose amphotericin B does not appear to provide a protective effect compared with placebo, but there does appear to be a possible effect in decreasing mortality.

Liposomal amphotericin B

The proven efficacy and improved toxicity profile of liposomal amphotericin B (AmBisome) prompted Tollemar and colleagues to evaluate the role of this lipid formulation of amphotericin B in preventing fungal infections after bone marrow transplantation (Tollemar et al. 1993). Thirty-six patients received the drug, at a dosage of 1 mg/kg for between 1 and 11 weeks, and 40 patients received no treatment. Fungal colonization decreased in the AmBisome group whereas it increased in the placebo group. By the end of prophylaxis, eight of 24 (33 percent) patients who received AmBisome were colonized compared with 18 of 29 (62 percent) patients in the placebo group. Presumed fungal infection occurred in five of 36 patients given AmBisome. None of these infections was fatal. In the control group, seven patients developed presumed fungal infection and two died. Proven fungal infection occurred in one patient receiving AmBisome (*Candida guilliermondii*) compared with three patients receiving placebo (*C. guilliermondii*, two; *C. albicans*, one). The study showed possible benefits regarding the reduction of proven fungal infection in the patients given AmBisome prophylactically. A beneficial effect of prophylaxis was found as none of the patients with a suspected fungal infection in the AmBisome group died with proven fungal infection compared with two placebo-treated patients.

The value of AmBisome as a prophylactic agent has been examined further by Kelsey et al. (1999) where AmBisome 2 mg/kg was compared with placebo in patients undergoing chemotherapy or bone marrow transplantation. Prophylaxis began on day 1 of chemotherapy and continued until neutrophils regenerated or infection was suspected. Of 161 evaluable patients, 74 received AmBisome and 87 received placebo. Proven fungal infections developed in no patients on AmBisome and in three patients on placebo. Suspected fungal infections requiring intervention with systemic antifungal therapy (usually amphotericin B) occurred in 31 patients (42 percent) on AmBisome and in 40 on placebo (46 percent)

Itraconazole

Itraconazole is an orally active triazole with a wide spectrum of activity which has been successfully used in the prevention of aspergillus infection.

Itraconazole has been compared with ketoconazole and nystatin in neutropenic patients in retrospective

analyses, and was found to be superior (reviewed by Beyer et al. 1994b). In a placebo-controlled, randomized trial of itraconazole prophylaxis, 400 mg/day reduced the overall incidence of proven fungal infection to nine of 83 neutropenic episodes (11 percent), compared with 15 of 84 episodes (18 percent) in the placebo arm (Beyer et al. 1994b). However, it should be noted that this effect was mainly the result of a reduction of systemic candida infections and was not statistically significant. The incidence of suspected or proven cases of invasive pulmonary aspergillosis was similar in both the prophylactic itraconazole (five of 83 or 6 percent) and the placebo (four of 84 or 5 percent) arms.

The absorption of itraconazole from the gastrointestinal tract varies within a wide range and is largely unpredictable, so itraconazole doses higher than 400 mg or therapeutic drug monitoring might be necessary for effective antifungal prophylaxis with this drug. There are a number of drugs that interfere with the absorption of itraconazole, among which are agents such as antacids that are commonly used in neutropenic patients. Further trials including larger numbers of patients are needed to make a definitive statement on the effectiveness of itraconazole for the prophylaxis of invasive pulmonary aspergillosis. To facilitate the prophylactic use of this agent, the availability of an itraconazole formulation with improved and more predictable bioavailability would clearly be beneficial.

ITRACONAZOLE ORAL SOLUTION

The known problems associated with the bioavailability of the capsule form in neutropenic patients have prompted the development of an oral solution of itraconazole. This bioavailablilty problem is thought to arise because gastrointestinal mucositis (following intensive cancer chemotherapy or radiotherapy) can make drug dissolution and absorption erratic, leading to abnormally low blood levels and lack of drug efficacy in some cases. It appears that this formulation has improved pharmacokinetics and more predictable bioavailability in neutropenic patients (Prentice et al. 1994; Michallet et al. 1998). In this study trough serum concentrations of itraconazole were measured weekly during prophylaxis with itraconazole liquid, 2.5 mg/kg b.i.d. in neutropenic patients undergoing treatment for hematological malignancies. From week 2 of prophylaxis, at least 84 percent of patients had itraconazole plasma concentrations higher than 250 ng/ml; this concentration is considered the minimum level required for antifungal efficacy. These pharmacokinetic findings have been confirmed by a much larger study where the value of prophylactic itraconazole solution was compared with fluconazole suspension (see below).

There has been a considerable expansion in the literature on the use of the itraconazole oral solution as prophylaxis against aspergillosis (see, for example, Foot et al. 1999; Glasmacher et al. 1999a, b; Kibbler 1999; Menichetti et al. 1999; Harrousseau et al. 2000; and reviewed in a *Journal of Antimicrobial Chemotherapy* supplement (in press).

ITRACONAZOLE LIQUID COMPARED WITH ORAL AMPHOTERICIN B PROPHYLAXIS

A randomized, double-blind, double-dummy study compared the efficacy of itraconazole liquid with oral amphotericin B capsules in patients with hematological malignancy and profound neutropenia (Harrousseau et al. 2000). The incidence of fungal infections was compared between groups and comparisons were also made of the frequency and time and initiation of intravenous amphotericin B rescue therapy. A total of 557 patients were randomized to receive either itraconazole liquid, 2.5 mg/kg body weight b.i.d. (n=281) or oral amphotericin B, 2×250 mg capsules q.i.d (n=276). Prophylaxis was initiated with chemotherapy and continued until the neutrophil count recovered or another study point was reached, up to a maximum of 8 weeks. Although not reaching statistical significance, there was a trend in favor of itraconazole liquid for proven invasive aspergillosis (five versus nine cases) as well as overall documented deep fungal infections including aspergillosis (eight versus 13 cases). One of eight patients died in the itraconazole group in contrast to five of 13 in the amphotericin B group. In this study plasma levels of itraconazole were measured and adequate levels (>250 ng/ml) were attained in at least 80 percent of patients 10–14 days after the start of treatment. After 4 weeks of prophylaxis, these levels were reached in 96 percent of patients.

ITRACONAZOLE LIQUID COMPARED WITH FLUCONAZOLE PROPHYLAXIS

Itraconazole in its liquid suspension form (5 mg/kg) has been compared with fluconazole suspension (100 mg) in a randomized trial where either itraconazole or fluconazole was given from the start of cytoreduction to neutrophil recovery in 581 neutropenic episodes in 445 adults receiving a bone marrow transplant or chemotherapy for hematological malignancy (Morgenstern et al. 1999). The dose of fluconazole suspension was chosen based on accepted practice at the time the study commenced. There were more proven cases of invasive aspergillosis in patients given fluconazole prophylaxis compared with itraconazole (four in the fluconazole arm, none in the itraconazole arm), demonstrating the superiority of itraconazole in suppressing invasive aspergillosis in immunocompromised patients. However, there were more gastrointestinal disturbances associated with itraconazole. These are most likely due to the cyclodextrin vehicle used in the solution formulation.

SAFETY OF ITRACONAZOLE LIQUID FOR ANTIFUNGAL PROPHYLAXIS

Safety information from data-on-file studies and summaries in abstract form is available for about 1 000 patients.

Adverse experiences observed frequently in these patients included nausea, vomiting, mucositis, diarrhea, and fever. Biochemical abnormalities frequently occurring for all treatment groups included decreases in calcium, potassium, and uric acid and increases in urea and bilirubin. The incidence and nature of adverse events reported in these studies to be definitely related to prophylactic drug treatment were similar for itraconazole liquid, oral amphotericin B, and placebo and were mainly gastrointestinal in nature.

ITRACONAZOLE ORAL SOLUTION AND CHILDREN

Itraconazole oral solution has been evaluated in neutropenic children undergoing an allogeneic bone marrow transplant (Foot et al. 1999). In an open study of antifungal prophylaxis in 103 children, patients received 5.0 mg/kg itraconazole oral solution per day. Prophylaxis was started at least 7 days before the onset of neutropenia and continued until neutrophil recovery. No proven systemic fungal infections occurred during the study but 26 patients received intravenous amphotericin B for antibiotic-unresponsive PUO. One patient received amphotericin B for mycologically confirmed esophageal candidosis. Three patients developed suspected oral candidosis but none was mycologically proven and no treatment was given. Serious adverse events occurred in 27 patients. The most common adverse events attributable to itraconazole were vomiting, abnormal liver function, and abdominal pain. This study indicates that itraconazole oral solution may be used as antifungal prophylaxis in neutropenic children.

PREVENTION

Prevention of aspergillosis is relatively difficult. Simple precautions – such as eliminating potted plants from patients' rooms and using barriers during hospital construction – are recommended. The use of high-efficacy particulate air (HEPA) filters appears to be the only currently effective means of decreasing the incidence of aspergillus infection.

The principles of environmental control of nosocomial aspergillosis are complex given that even HEPA units are not completely effective in preventing disease. Fungal exposure would be more precisely studied using a personal air sampler for the patient, but there is no fungal sampler currently available which can be used in this way, and there are also severe technical limitations on the duration of the sampling time of available fungal samplers (Morris et al. 2000; Thio et al. 2000). Alternatively, a systematic program of longitudinal patient and environmental surveillance may predict cases of invasive aspergillosis. Indeed, there appears to be a correlation between the recovery of *Aspergillus* spp. from the nose and mouth of patients in an open hematology ward and an elevated number of conidia in the air (Richardson et al. 2000).

The relationship between aspergillosis in predisposed patients and building work is also complex. Hospitals are buildings of continuous change and adaptation, so construction is an inevitable prospect which may extend throughout the year. Whether or not this activity is complicated by an outbreak of infection in the susceptible patients nearby, or is a risk related directly to the amount of disruption or some other factor, is unknown. In one study, an increase in the number of patients with invasive aspergillosis could not be explained by an increase in the number of aspergillus conidia in the outside air (Leenders et al. 1998). Genotyping of the isolates from the unit where the survey was carried out showed that clonally related isolates were persistently present for more than 1 year. Clinical isolates of *A. fumigatus* obtained during the outbreak period were different from the clones normally persistent in that environment.

Currently, the environmental mycology of most outbreaks of nosocomial aspergillosis is poorly defined. However, the development of molecular biology techniques more directly applicable to *Aspergillus* spp. may help resolve some of these difficulties.

Aspergillus spp. have a major reservoir in organic debris, bird droppings, dust, and building material. The principal approach in the prevention of aspergillosis is to minimize patients' exposure to aspergillus conidia by filtering air or initiating some form of patient isolation (Sherertz et al. 1987; Rhame 1991; Hay 1993). Further steps consist of elimination of obvious sources of aspergilli, such as removing plants from the surrounding environment of a patient. In some instances surface disinfection with copper-8-quinolinolate has been reported to be effective. Susceptible patients should not be treated in areas where there is construction or demolition activity, and if such activities are under way, measures should be instigated to seal these sites to prevent air exchange with the patients' environment.

Certain foodstuffs, such as cereals, nuts, and spices, e.g. ground black pepper, have been found to be contaminated with aspergilli and should not be offered to patients at risk of developing invasive pulmonary aspergillosis (reviewed by Beyer et al. 1994b). Although outbreaks of invasive aspergillosis have been associated with construction within or around a hospital, the precise source of the fungus is occasionally difficult to trace with certainty (Opal 1986; Iwen et al. 1994; Anderson et al. 1996). There have been few studies that have prospectively examined the aeromycology in and around a hospital during major building alterations and then compared these findings with samples from patients and the incidence of invasive aspergillosis (reviewed by Beyer et al. 1994b).

In a seminal study (Goodley et al. 1994), the authors took advantage of the opportunities that arose during

widespread building operations around their hospital where several groups of patients seemed at risk of fungal infection – in wards for renal transplantation, bone marrow transplantation, oncology, and intensive care. Air samples were taken in these wards (by SAS Sampler, pbi International, Milan, Italy) and various outdoor sites around the hospital, at specific sites throughout the hospital, sequentially throughout the year as well as in particular areas during periods of construction activity. Nasal swabs were also taken from patients for comparison with the air sampling results. The most commonly isolated fungal species was *A. fumigatus*. Nasal swabs were positive in 12 of 188 samples – 11 *A. fumigatus* and one *Aspergillus sydowi*. Most of the air samples cultured less than 10 c.f.u./m^3 throughout the year. A peak of higher counts occurred in March (190 c.f.u./m^3, confirmed at various sites) which could not be explained either by building work or by meteorology. Eight of the positive nasal swabs were obtained during March; three cases of invasive aspergillosis developed through the year and did not seem to be related to the spell of higher spore counts. One of the buildings was demolished, but there was no significant rise in spore counts and no change in the background pattern of fungal isolation in the wards or the corridors. Air sampling was repeated over the following year when a peak was recorded in June at 90 c.f.u./m^3, and very similar low levels throughout the rest of the year. The authors' interpretation of the results was that, because cases of invasive aspergillosis seemed to develop at low spore levels, then all highly susceptible patients should have protective isolation (HEPA ventilation and sterile management procedures). Routine nasal swab sampling was not proposed as an alternative to air sampling. Avoidance measures appear to be appropriate if minimal exposure is the only component necessary to induce invasive aspergillosis in transplant recipients.

The debate concerning the value of laminar air flow (LAF) rooms in protecting high-risk patients from *Aspergillus* has continued. Wald and coworkers conducted a retrospective analysis of aspergillosis in bone marrow transplant recipients (Wald et al. 1997). One of the conclusions of this study was that the use of LAF rooms is protective against early, but not late, aspergillosis, during the transplant course. The conclusions in this study were questioned by Viscoli (1998), who was of the opinion, based on personal experience and the existing literature, that even if it was shown that LAF rooms were associated with a reduced risk of early aspergillosis, it is unlikely that this benefit resulted from the use of the LAF room system as a whole, but rather by the air filtration through the HEPA filters. The opinion was offered that the use of LAF rooms in bone marrow transplant recipients should not be encouraged without convincing supporting data.

A preventative strategy has been proposed by a consortium of The Mycologic Study Group of the French Society of Hematology and The Research Group on Fungal Infections, and The European Group for Research on Biotypes and Genotypes of *Aspergillus* Network (Gangneux et al. 2002). The salient points of this strategy are as follows:

- Air-control measures remain crucial for the reduction of environmental dissemination of fungal conidia. The consortium's premise is that the nosocomial origin of aspergillosis has been convincingly demonstrated in epidemic situations. A number of investigations have shown that the concentration of *Aspergillus* spp. and other fungi in the air in a hematology unit correlated with the incidence of invasive aspergillosis in nonepidemic situations. Thus, it is strongly recommended that patients who are at high risk of infection benefit from the measures put forth by the Centers for Disease Control and Prevention, that is, the use of HEPA filtration, use of LAF systems, high rates of room-air change, use of positive pressure, and use of well-sealed rooms.
- Air-control efficiency must be monitored. Several years ago, a regular monitoring of environmental fungal contamination (for *Aspergillus* and other airborne fungal species) was started, with two major goals: to detect increases in conidia density and to assess air-control efficiency. Environmental monitoring requires the following:
  - air sampling with an efficient biocollector
    surface sampling with contact petri dishes or swabs, which is a simple and efficient monitoring method that can detect minor contamination, even when concomitant air samples test negative for fungi
  - sampling of patient rooms that are equipped with HEPA filters, with or without LAF, and sampling of all parts of the ward that are provided with air filtration and positive pressure (particularly corridors)
  - use of guidelines for patient management and cleaning procedures in protective environments, which should be adapted according to the results of monitoring.
- Determination of the baseline values of air and surface concentrations of *Aspergillus* spp. and other fungal conidia is essential for valuable assessment of any further increase in fungal contamination. Given the genetic diversity of *A. fumigatus* isolates, and given the current limitations of molecular typing methods to localize the fungal source or to date the infection, environmental sampling is not, in the authors' opinion, simply a means of comparing environmental isolates with clinical isolates.
- The sources and routes of conidia transmission are unclear. It has been suggested that aspergillosis is waterborne, and that nosocomial aspergillosis can be airborne from water sources in the hospital setting.

However, this is not a unversal finding. It is apparent that the environmental risk of invasive aspergillosis linked to water should be interpreted according to the local situation, namely, the source of water (underground versus surface water). In addition, because humidity favors fungal growth, high fungal densities near water sources may simply reflect the presence of conidia in the air or on surfaces and indicate the need for new cleaning procedures. Furthermore, the biotope of *A. fumigatus* differs from that of *Fusarium* and *Acremonium* spp.

Alternative sources of conidia inhalation should not be neglected. These sources include the clothing of visitors and medical staff as well as personal and medical materials. Therefore, specific preventive measures may be appropriate. The gastrointestinal route of infection is rarely considered; however, a high rate of food contamination by filamentous fungi, such as *Aspergillus* spp. and zygomycetes, has been reported. The existence of isolated gastrointestinal filamentous fungal infection without pulmonary or disseminated infection supports the hypothesis that, in addition to the risk of conidia inhalation, contact with food or water can lead to conidia absorption.

The authors' conclusions and recommendations in this consensus document are many-fold. Aspergillosis mainly occurs in neutropenic patients. Air-control measures are presently the most effective way of significantly reducing the incidence of nosocomial aspergillosis. Although they are expensive and only partially effective, these measures should not be called into question, as shown by their protective effect against early infections after bone marrow transplantation. However, the efficiency of air-control measures should be continuously monitored by regular measurement of environmental levels of fungal conidia. This approach is strongly recommended in units that use air-control measures, as are specific investigations of cases of aspergillus infection. However, there should be more investigation and control of alternative sources of contamination. Prevention of delayed acquired aspergillosis is even more difficult: control of environmental sources of contamination and follow-up of aspergillus colonization are difficult outside the hospital setting, and, until now, there has been no demonstration that any antifungal drug or cytokine can significantly prevent or reduce the risk of aspergillosis in patients who are at risk of infection.

Deep phaeohyphomycosis

CHESTER R. COOPER, JR

Phaeohyphomycosis – histopathological and clinical concepts	2	Biological aspects related to pathogenesis	8
Clinical manifestations of DSP	4	Summary and future directions	8
Histopathology and diagnosis of DSP	6	References	9
Treatment of DSP	7		

The incidence of fungal infections in humans has been rising for the past several decades due to a number of diverse reasons, some of which include social and geopolitical factors (Dixon et al. 1996; Cooper 2002). The primary dynamic leading to this marked increase in fungal infections has been the expanding population of immunocompromised individuals. Moreover, the etiologic agents in many of these cases are misplaced saprotrophs, i.e. opportunistic pathogens. Such organisms tend to be benign towards humans and animals, rarely causing disease. These fungi exist in nature by gathering nutrition via consuming organic debris or through parasitic relationships with living plants. Yet, under the proper conditions, these opportunists can readily exploit a dysfunctional mammalian immune system to cause severe cutaneous, subcutaneous, and deep-seated disease.

One group of opportunistic fungal pathogens is characterized by the single shared characteristic of possessing a darkly pigmented appearance. The pigment has been demonstrated to be a melanin produced via a pentaketide pathway (Wheeler and Bell 1988). Traditionally, the dark color of these fungi caused them to be designated as 'dematiaceous'. However, the use of the word 'dematiaceous' to describe melanized fungi has been argued to be epistemologically incorrect (Pappagianis and Ajello 1994). Subsequently, the term 'phaeoid' has been used to replace the prior designation. Nonetheless, the descriptive word 'dematiaceous' has been so entrenched within the mycological literature that it is still used today in synonymy with the term 'phaeoid'. In this chapter, both expressions will be used interchangeably. Despite the semantic arguments, an important point needs to be emphasized with regard to the use of either designation – both have no real taxonomic significance. Rather, these terms refer to a heterogeneous collection of generally unrelated fungi that share the common phenotypic trait of being darkly colored under normal laboratory conditions.

The phaeoid (dematiaceous) fungi are a curious group of organisms capable of causing a wide array of clinical pathologies ranging from the superficial to the deep-seated infections (Perfect et al. 2003; Sanche et al. 2003). The focus of this chapter is placed upon those molds that cause the latter type in humans and animals. Such infections have been designated as visceral, systemic, or disseminated phaeohyphomycosis. In this chapter, these terms are reserved to describe a particular type of phaeohyphomycosis. The more general phrase, deep-seated phaeohyphomycosis (DSP), is proffered in their place. As discussed below, DSP can be divided into disseminated phaeohyphomycosis as well as a second clinical entity, cerebral phaeohyphomycosis. While sharing many features, these two categories of disease caused by dematiaceous fungi are disparate in several epidemiologic, etiologic, and clinical aspects. These differences are presented, as are the general diagnostic and intervention methods for both types of DSP. Also, the potential relationship of certain biological features to virulence is discussed. However, a comprehensive description regarding the mycology and taxonomy of the etiologic agents of DSP is not presented. For this, as well as a fuller discourse pertaining to superficial, cutaneous,

and subcutaneous diseases caused by pigmented fungi, the reader is referred to White piedra, black piedra and tinea nigra; and 18, Chromoblastomycosis in this volume as well as several recent reviews (Kwon-Chung and Bennett 1992; Matsumoto and Ajello 1998; Brandt and Warnock 2003; Perfect et al. 2003; Sanche et al. 2003; Schell et al. 2003).

PHAEOHYPHOMYCOSIS – HISTOPATHOLOGICAL AND CLINICAL CONCEPTS

Dematiaceous fungi are etiologic agents responsible for a number of diverse diseases in humans and animals (Table 1). Though darkly pigmented in culture, not all these fungi appear so in vivo. In addition, studies have indicated that some fungal pathogens traditionally considered not to be phaeoid (e.g. *Cryptococcus neoformans*) do apparently either make minute amounts of melanin or have the ability to do so in vivo (Kimura and McGinnis 1998). This has led to a range of difficulties and confusion in the diagnosis of these diseases and their corresponding causative agents (Kwon-Chung and Bennett 1992).

To help resolve these problems, Ajello and colleagues proposed the terms 'phaeohyphomycosis' and 'hyalohyphomycosis' to distinguish between those fungal infections caused by phaeoid and hyaline molds, respectively, and which exhibit a predominant filamentous morphology in vivo (Ajello et al. 1974). In particular, these medical mycologists envisioned phaeohyphomycosis to encompass cutaneous, subcutaneous, and systemic infections in which the etiologic agent 'develops in the host tissues in the form of dark-walled dematiaceous septate mycelial elements.' Thus, this designation defined the infection based upon its histopathology rather than its clinical presentation. However, the original definition was limited to hyphomycetous fungi, i.e. a class of molds taxonomically placed within the form-division Fungi Imperfecti [Deuteromycota; asexual (mitosporic) fungi]. As new cases of phaeohyphomycosis were reported, it became clear that not all were hyphomycetes. Subsequently, Ajello amended the definition of phaeohyphomycosis to include infections caused by fungi belonging not only to the form-class Hyphomycetes, but also those grouped within the form-class Coelomycetes (form-division Fungi Imperfecti) and division Ascomycota [fungi that form sexually derived spores (meiospores) within an ascus] (Ajello 1981).

As conceived, phaeohyphomycosis was intended to exclude the well-established disease states that also featured the formation of phaeoid hyphae in tissue, e.g. tinea nigra, chromoblastomycosis, sporotrichosis, and eumycotic mycetoma. These latter diseases are distinct, separate entities having their own unique clinical and histopathological presentation in addition to etiologic differences. The reader is referred to the appropriate chapters within this book (White piedra, black piedra and tinea nigra; Chromoblastomycosis; Sporotrichosis; and Eumycetomas, respectively) for a more in-depth discussion of these disease states.

As a cosmopolitan disease, phaeohyphomycosis mainly afflicts adults among whom many are immunocompromised. Underlying conditions that contribute to infection by dematiaceous fungi include tuberculosis, diabetes, cancer, tissue transplantation, and use of corticosteroids or other immunosuppressive drugs, surgery, and a number of other conditions including acquired immunodeficiency syndrome (AIDS) due to the human immunodeficiency virus (HIV) (Table 2).

Many cases of phaeohyphomycosis appear in the perfectly healthy and may have no evident exposure history. These non-life-threatening infections include focal-subcutaenous, mycotic keratitis, and paranasal sinus infections. Subcutaneous phaeohyphomycosis is a common site of infection and is generally thought to occur as a result of traumatic implantation of fungal material from contaminated plants or soil. The most common outcome of this type of inoculation is a localized cyst or abscess that appears primarily as a single, discrete and asymptomatic or mildly painful nodule. From this entity, granulomatous reactions may occur and the disease may on occasion progress to produce verrucose plaques reminiscent of chromoblastomycosis.

Table 1 *Fungal infections with phaeoid etiologies*

Infection
Black piedra
Chromoblastomycosis
Eumycotic mycetoma
Phaeohyphomycosis
Pseudallescheriasis
Sporotrichosis
Tinea nigra
Zygomycosis

Table 2 *Risk factors associated with phaeohyphomycosis*

Risk factor
Bone marrow transplantation
Cancer
Cardiac surgery
Chronic ambulatory peritoneal dialysis
Corticosteroid therapy
Diabetes
Fungal sinusitis
HIV infection
Intravenous drug use
Neutropenia
Solid organ transplantation
Trauma to skin or soft tissues
Tuberculosis

Mycotic keratitis also is a common site for this fungal infection where asexual spores of these fungi that are common in our environment can contaminate a corneal abrasion following trauma. Paranasal sinus infections are also frequently diagnosed. They present with sinuses impacted with a phaeohyphomycotic ''fungoma'' seen in biopsy. Frequently, there is an allergic host response to the fungus as evidenced by the presence of eosinophils. Rarely is this type of sinus infection highly invasive. These non-life-threatening infections are caused by the same genera/species that cause deep-seated infections implying the importance of the host in the dynamics of the phaeoid fungus/host interactions.

By comparison, DSP is rare. Recently, Revankar and colleagues (Revankar et al. 2002, 2004), as well as Filizzola et al. (Filizzola et al. 2003), published reviews focused on DSP. Case reports from 1996 through 2002 were obtained from citations listed in the Medline database (National Library of Medicine, Bethesda, MD). Additional cases of DSP were reviewed from other references cited in these reports. Though not fully comprehensive, since non-English language literature was generally excluded, these reviews clearly separate DSP into two broad groups of infections. In one category of DSP, infection is disseminated throughout the body and may involve the central nervous system (CNS). Most individuals affected with disseminated disease tend to have decreased host immunity or possess other risk factors. A second distinct type of DSP is generally restricted to the CNS. Curiously, about half of the victims of cerebral phaeohyphomycosis do not appear to possess underlying conditions or risk factors predisposing them to infection. Both types of DSP are discussed in greater detail below.

It is significant to note, however, that DSP appears to involve only a subset of fungal species listed as etiologic agents of phaeohyphomycosis (Matsumoto et al. 1994; Matsumoto and Ajello 1998). Of the more than 100 species among the 60 genera associated with infection by dematiaceous fungi, about a third are known to cause DSP (Table 3). [The specific epithets presented in Table 3 and elsewhere in the text represent the currently accepted nomenclature for a particular fungal species. Previously employed binomials for fungal species causing phaeohyphomycosis, as well as a detailed mycological description of these etiologic agents, can be readily found in several publications (Kwon-Chung and Bennett 1992; Matsumoto and Ajello 1998; Perfect et al. 2003; Sanche et al. 2003; Schell et al. 2003).] This list should not be considered comprehensive since new cases of DSP are likely to be reported that involve species not listed. Moreover, not all medical mycologists may agree with the inclusion of certain fungi as agents of phaeohyphomycosis (see discussion below). Nonetheless, the fungal species presented here typify those that have been adequately documented as the major etiologic agents of DSP.

Table 3 *Fungal species associated with DSP* [a]

Fungal species
Acropophialophora
Alternaria infectoria
Amium leproinum
Aureobasidium pullulans
Bipolaris
B. australiensis
B. hawaiiensis
B. specifera
Bipolaris spp.
Chaetomium
C. atrobrunneum
C. globosum
C. perlucidum
C. strumarium
Cladophialophora
C. bantiana
C. devriesii
C. modesta
Cladophialophora spp.
Cladosporium cladosporoides
Curvularia
C. geniculata
C. lunata
C. pallescens
Exophiala
E. castellanii
E. jeanselmei
E. mansonii
Exserohilum rostratrum
Fonsecaea pedrosoi
Hormonema dematioides
Lecythophora mutabilis
Microascus cirrosus
Myceliophthora thermophila
Nodulisporium spp.
Ochroconis gallopavum
Phaeoacremonium parasiticum
Phialemonium curvatum
Phialophora richardsiae
Rhamichloridium obovoideum
Rhinocladiella atrovirens
Scopulariopsis
S. brumptii
Scopulariopsis spp.
Scytalidium dimidiatum
Wangiella dermatitidis

a) Data collected from Revankar et al. (2002, 2004); Barron et al. (2003); Filizzola et al. (2003); Teixeira et al. (2003).

The list of phaeohyphomycotic agents given in Table 3 is notable in its exclusion of *Scedosporium* spp. [*Scedosporium apiospermum* (anamorph of *Pseudallescheria boydii*) and *Scedosporium prolificans* (formerly *Scedosporium inflatum*)] as agents of DSP.

The inclusion of these fungi as a cause of phaeohyphomycosis has been a source of controversy and needless consternation (Matsumoto et al. 1994). Some investigators persist in embracing *Scedosporium* spp. in the etiology of phaeohyphomycosis (Revankar et al. 2002, 2004; Schell et al. 2003). Others seemingly do not agree with this position, yet continue to include this organism in the description of possible causative agents (Matsumoto and Ajello 1998; Perfect et al. 2003). Moreover, some recent publications clearly state that *Scedosporium* is an agent of hyalohyphomycosis (McGinnis and Ajello 1998; Tadros et al. 1998; Walsh 1998; Torres and Kontoyiannis 2003) or the form-genus is conspicuously omitted as a phaeohyphomycotic agent (Sanche et al. 2003). The confusion is further compounded by the fact that several authors of the above-cited publications have taken both positions.

Perhaps the source of this chaos lies in the misapplication of the true, intended definition of phaeohyphomycosis. As noted above, this clinical entity is based upon the histopathological observation of 'dark-walled dematiaceous (i.e. phaeoid) septate mycelial elements' in diseased tissue (Ajello et al. 1974; Ajello 1981). As dematiaceous fungi, *Scedosporium* spp. do form a melanin-like color in culture (Schell et al. 2003). These species also stain positive for melanin in vivo, using the Fontana–Masson silver stain, which is specific for such pigments (Wood and Russel-Bell 1983). The histopathology of tissues infected with *Scedosporium* spp. is also similar to phaeohyphomycosis, but more strongly resembles the dichotomous hyphal branching seen in aspergillosis (Chandler and Watts 1987; Cooper and Salkin 1993). However, the hyphae observed in these tissues are hyaline except when aggregates are formed such as in a pulmonary 'fungoma' (fungus ball). Brown conidia are sometimes observed in the latter. Yet, a fungoma due to *Scedosporium* clearly represents a separate clinical presentation that tends not to be invasive (Cooper and Salkin 1993). Therefore, despite the occasional presence of pigmentation, inclusion of *Scedosporium* spp. as etiologic agents of phaeohyphomycosis is inconsistent with the present definition of this disease state. Unless the description of this term is amended formally, clinicians should be aware that not all phaeoid fungi are agents of phaeohyphomycosis. Indeed, some melanized fungi cause infections better attributed to markedly different, classical presentations (e.g. sporotrichosis, chromoblastomycosis, etc.). At the risk of eliminating more fungi listed in Table 3, if a particular mold species does not consistently form dark-colored hyphae in vivo, it should be considered an agent of hyalohyphomycosis. Such is the case with *Scedosporium* spp. and is a position more in line with the accepted definitions first proposed by Ajello and colleagues (Ajello et al. 1974; Ajello 1981).

This same argument, however, might be used against other dematiaceous fungi generally acknowledged by medical mycologists to be phaeohyphomycotic agents. For example, species of *Bipolaris*, as well as other fungi, do not always produce pigmented fungal elements in tissue. In one such case involving *Bipolaris spicifera*, the clinical isolate did form dark-colored hyphae in experimentally infected mice (Yoshimori et al. 1982). Given the ever-increasing spectrum of pathogenic dematiaceous fungi and the inconsistent nature of pigment production in vivo, perhaps the definitions of phaeohyphomycosis and hyalohyphomycosis need to be re-evaluated. However, except in the clinical presentation of fungoma, *Scedosporium* spp. do not produce visible melanin in vivo despite the large number of reports of disease involving these species. Collectively, these cases certainly outnumber those of phaeohyphomycosis caused by the most frequently encountered dematiaceous fungi in which melanin is consistently visible in tissues.

CLINICAL MANIFESTATIONS OF DSP

DSP can be divided into the separate clinical presentations of systemic disease and cerebral involvement. These different manifestations share the same histopathological concept – the presence of darkly pigmented hyphae in vivo. In broad terms, many of the symptoms, treatment outcomes, and types of patients are common to both. Yet, each does have unique aspects that distinguish one from the other. The following succinct descriptions compare both the mutual and exclusive aspects of disseminated and cerebral phaeohyphomycosis.

Disseminated phaeohyphomycosis

Compared to cutaneous and subcutaneous forms of phaeohyphomycosis, there are relatively few reports of disseminated disease by phaeoid fungi in the medical literature. Although infrequent in morbidity, disseminated phaeohyphomycosis deserves special consideration as a separate disease type given its level of mortality (Revankar et al. 2002). Disseminated disease results by the spread of the dematiaceous pathogen from a previously colonized or infected body site (Kwon-Chung and Bennett 1992; Brandt and Warnock 2003; Perfect et al. 2003; Sanche et al. 2003). Trauma or surgery is typically a cause of cutaneous or subcutaneous infection sites. In addition, dissemination can originate from the lungs or infected sinus tissue following inhalation of fungal cells or conidia. Under the appropriate circumstances, direct extension from the sinus or hematogenous spread of the fungus to one or more distant sites of the body can result in visceral infections of the heart and heart valves, brain, joints, bone, kidney, liver, lymphatics, pancreas, and other organs. Cases of dialysis-associated peritonitis have also been shown to be caused by dematiaceous fungi.

Recently, Revankar and co-workers (Revankar et al. 2002) reviewed 72 case studies of disseminated phaeohyphomycosis published in the English language literature between 1996 and 2001. The authors considered each of these cases valid based upon the following criteria:

- the presence of a clinical syndrome consistent with disseminated disease
- histopathological evidence of a true infection
- the recovery and identification of a dematiaceous fungus.

Included in this review were 30 infections caused by *S. prolificans*. As previously noted, infection by this fungus is better termed hyalohyphomycosis. Therefore, the 30 cases cited by these investigators are excluded from the following discussion. The remaining 42 infections, though drawn from a selected pool of reports, do represent a general overview of disseminated disease caused by dematiaceous fungi.

Most of the 27 species cited by Revankar et al. (2002) as etiologic agents are described in single case reports. This reflects the uncommon nature of disseminated phaeohyphomycosis. Of the 42 patients studied, 35 (83 percent) possessed some risk factor predisposing them to infection, including two cases of AIDS. In addition, some of the apparently normal individuals exhibited eosinophila. This suggests that certain patients have developed a poor TH2 response, thereby hindering cell-mediated immunity and inadvertently promoting dissemination of the infection. Clinically, the most common symptoms among the 42 affected individuals included fever, skin manifestations, respiratory complaints, and neurological problems. Sepsis and gastrointestinal symptoms were also recorded. With regard to the sites of infection, half the cases involved the lungs. Other significantly affected organs included the brain, heart/heart valve, kidney, liver, and lymph nodes. In some instances, the spleen and pancreas were involved. Death resulted in 29 (70 percent) of the 42 cases, including five patients who did not receive antifungal therapy. The remaining 13 patients received surgical intervention, antifungal therapy, or both. Amphotericin B alone or in combination with other drugs and/or surgery was used in 10 cases. However, specific therapeutic recommendations based upon the outcome of these treatment regimens are not possible given the general resistance of dematiaceous fungi to amphotericin B as well as the number of diverse species implicated in these infections. Yet, the results do make it clear that no single drug or combination therapy improved mortality rates.

Cerebral phaeohyphomycosis

Cerebral infections by phaeoid fungi represent a specialized type of DSP. For instance, most of the commonly encountered dematiaceous fungi causing cerebral phaeohyphomycosis produce mainly brain abscesses as opposed to disseminated disease (Kwon-Chung and Bennett 1992; Filizzola et al. 2003; Sanche et al. 2003; Revankar et al. 2004). These fungi include *Cladophialophora bantiana*, *Ochronconis gallopavum*, *Ramichloridium obovoideum*, *Wangiella dermatitidis*, *Curvularia* spp., and *Bipolaris* spp. Studies of human infections and in animal models have shown with certainty that *C. bantiana* is neurotropic, i.e. it has a propensity to cause infection of the CNS (Dixon et al. 1987a, b). The remaining major etiologic agents also possess neurotropic tendencies (Walsh et al. 1987). Moreover, whereas disseminated phaeohyphomycosis mainly afflicts individuals having immunodeficiencies or other risk factors, nearly half of patients with cerebral phaeohyphomycosis are immunocompetent. There does appear to be some symptomatic overlap in that disseminated phaeohyphomycosis can also involve the CNS. However, the latter type of phaeohyphomycosis is usually accompanied by disease of multiple organs and typically originates by hematogenous spread from a primary focal infection. Cerebral phaeohyphomycosis, particularly in apparently normal hosts, usually does not involve other organs. Hence, these observations and the limited etiologic spectrum lend special consideration to cerebral phaeohyphomycosis as a separate type of DSP.

CNS infections by phaeoid fungi are distributed worldwide. Presumably, most infections that lead solely to brain abscess or meningitis occur initially from the inhalation of fungal propagules. Following colonization in the lung, the fungus is transferred via a hematogenous route to the CNS. Alternatively, chronic fungal sinusitis may serve as the cause of CNS invasion (Sanche et al. 2003; Schell et al. 2003). Phaeohyphomycotic agents commonly associated with this condition include species of *Bipolaris*, *Exserohilum*, *Curvularia*, *Alternaria*, and *Cladosporium*.

Clinical symptoms of cerebral phaeohyphomycosis include headache, fever, seizures, and neurological deficits. In contrast to bacterial infections of the CNS, these symptoms do not always occur together. Sudden onset of blindness may also occur mainly in those infections by *Bipolaris* or *Curvularia* due to compression of the optic nerve (Walsh 1998). Again, immunocompetent patients tend not to have signs of organ infection other than the CNS.

Abscesses in cerebral phaeohyphomycosis may occur singly or as multiple masses (Perfect et al. 2003; Sanche et al. 2003). The frontal lobe is the most common site for abscess formation, but other areas of the brain can be affected. Another type of presentation, either alone or in conjunction with abscess development, is meningitis. Reports of dematiaceous fungi in CSF, though very rare, have been documented.

Two independent surveys of the English-language literature from 1996 through 2002 have been published that describe authentic cases of cerebral phaeohypho-

mycosis. One survey focused solely on infection in the immunocompetent host (Filizzola et al. 2003), whereas the other was broader in scope (Revankar et al. 2004). Though not fully comprehensive, these two reviews provide a well-documented synopsis of the current status of cerebral phaeohyphomycosis. Collectively, both study groups cited 109 cases of cerebral phaeohyphomycosis. Each report was considered bona fide if it met specified clinical, histopathological, and mycological criteria that define phaeohyphomycosis. However, a single case due to the hyalohyphomycotic agent *S. prolificans* was incorrectly included (Revankar et al. 2004). Therefore, among the 108 valid case reports, a total of 25 phaeoid fungal species were identified. The number of infected males was three times that of females. Of all the patients afflicted with cerebral phaeohyphomycosis, 55 percent were immunocompetent. Only a single individual was HIV positive among those predisposed to infection. Overall mortality was 73 percent amid the 97 patients for whom an outcome was reported. Nearly the same mortality was reported for both apparently normal and at-risk individuals (74 and 71 percent, respectively). When cases caused by selected etiologic agents are considered, some marked differences in mortality exist (Table 4). With regard to *C. bantiana*, which was responsible for 44 percent of the cases reported, overall survival of the 42 patients followed was 29 percent. Interestingly, compromised individuals survived at a higher rate (45 percent) than normal hosts (23 percent) (Filizzola et al. 2003; Revankar et al. 2004). Though not quite significantly different (P=0.06), and the underlying reasons unclear, the limited data set does seem to suggest that immunocompetent persons with cerebral phaeohyphomycosis due to *C. bantiana* face a greater mortality risk. Comparable overall levels of mortality resulted from infections with *Bipolaris* spp. and *O. gallopavum*, though much fewer cases have been observed. By contrast, virtually all cases of cerebral phaeohyphomycosis involving *R. obovoideum*, *W. dermatitidis*, *Fonsecaea pedrosoi*, and *Chaetomium* spp. were fatal regardless of host immune status.

HISTOPATHOLOGY AND DIAGNOSIS OF DSP

Phaeohyphomycotic lesions exhibit distinct histopathologies depending upon the clinical form of the disease (McGinnis 1983; Chandler and Watts 1987). Moreover, the pathological features are similar regardless of the etiologic agent. In DSP, lesions of a given organ may occur as single or multiple abscesses that broadly resemble the subcutaneous cystic form of phaeohyphomycosis. Alternatively, infection may consist of an inflammatory infiltrate with the presence of necrosis. When formed, abscesses are usually circumscribed and encapsulated granulomas, the walls of which comprise epithelial histiocytes and giant cells surrounded by connective tissue. A pyogenic inflammatory response is common as well. The centers of the granulomas contain necrotic debris, fibrin, and degenerated polymorphonuclear cells.

Within the necrotic debris and inflammatory infiltrates, as well as in the giant cells, fungal elements can be observed. The morphology of these fungi may consist of septated hyphae (2–6 μm in diameter), pseudohyphae (moniliform hyphae), budding yeasts, enlarged subglobose cells (up to 25 μm in diameter), chlamydoconidia, or spherical cells divided internally in a single plane. The latter resemble the muriform (sclerotic) cells characteristically found in chromoblastomycosis (McGinnis 1983; Chandler and Watts 1987), but differ in having thinner cell walls and a single planate septum. Lesions may contain one or more of the above structures. The brown pigment in the walls of these fungal cells may be visible in hemaotoxylin and eosin-stained tissue sections. This is not always the case, however. For example, the fungal elements of the species of *Bipolaris*, *Curvularia*, and *Alternaria* often appear hyaline in vivo although these fungi do form melanin in culture. In such circumstances, the Fontana–Mason stain will help reveal if a potential dematiaceous fungus is present (Wood and Russel-Bell 1983). Still, fungi other than those causing phaeohyphomycosis (and the similar clinical entity, chromoblastomycosis) also stain positive using this method (Kimura and McGinnis 1998).

Table 4 *Survival rates of cerebral phaeohyphomycosis patients infected with selected etiologic agents*[a]

	Number of deaths per total number of patients				
Fungal species	Number of cases	Normal host	Compromised host	Outcome unknown	Overall death rate (%)
C. bantiana	48 (44%)	24/31	6/11	6	71
R. obovoideum	13 (12%)	4/4	5/5	4	100
Bipolaris spp.	9 (8%)	2/4	3/4	1	63
F. pedrosoi	5 (5%)	1/1	2/3	1	75
Chaetomium spp.	5 (5%)	0/0	5/5	0	100
O. gallopavum	5 (5%)	0/0	3/5	0	60
W. dermatitidis	4 (3%)	4/4	0/0	0	100

a) Data taken from Filizzola et al. (2003) and Revankar et al. (2004).

A presumptive diagnosis of DSP can be made if brown fungal elements are observed in vivo and are accompanied by a clinical presentation consistent with the disease. However, such observations do not indicate which pathogen is involved. It is critical to the therapeutic intervention in cases of systemic and cerebral phaeohyphomycosis that the etiologic agent be identified. Because phaeoid fungi can occur as contaminants, documentation that an infection is present requires that cultures be obtained from otherwise sterile body sites or from tissue in which the histopathology is consistent with DSP. For a fuller treatment regarding culture and identification methods for other major species of melanized fungi that cause phaeohyphomycosis, several resources can be consulted (McGinnis 1980; Dixon and Polak-Wyss 1991; Matsumoto and Ajello 1998; Sanche et al. 2003; Schell et al. 2003). In addition to identifying isolates by morphological characteristics, other phenotypic measurements that can be used include nitrate and carbohydrate assimilation tests, exoantigen tests, proteolytic activity, growth temperature response, etc. Generally, the biochemical and exoantigen methods have limited applications in the identification of dematiaceous fungi.

It is important to note that there is a paucity of molecular methods to identify dematiaceous fungi. Virtually all are based upon the identification or amplification of specific DNA from ribosomal or internal transcribed spacer regions (Abliz et al. 2003, 2004a, b; Hall et al. 2004). One commercially available method, the MicroSeq D2 large-subunit rDNA sequencing kit, shows some promise. Of the 80 phaeoid fungi tested, representing 36 separate species, 52 (65 percent) yielded identifications consistent with those derived by classical phenotypic methods (Hall et al. 2004). Also, this molecular-based identification method appears equivalent to the phenotypic procedures in terms of costs. However, more isolates of the same and different species need to be tested to determine the true efficacy of this kit. Despite the generally good results with this kit, though, it remains essential for the near future in medical mycology that requisite laboratory skills in the identification of fungi by more traditional phenotypic means continue to be developed and maintained.

TREATMENT OF DSP

The mortality rate of individuals having DSP, even if treated, is grimly high compared to that of persons receiving therapy for other forms of phaeohyphomycosis. Moreover, because publications on DSP have reported individual cases of disease and treatment, if any, there is relatively little information to recommend global treatment strategies. The situation is further exacerbated by the fact that these case reports collectively describe a diverse spectrum of species rather than a series of frequently encountered pathogens. It seems that each case of DSP should be approached therapeutically based upon its own particular circumstances. Nonetheless, the collective evidence discussed below seems to suggest some general guidelines for treatment of DSP as well as hope that newer antifungal agents will aid in the cure of infections caused by the phaeoid fungi.

Treatment of disseminated phaeohyphomycosis by surgical means is typically impractical. Prior to the development of effective azole and echinocandin drugs, chemotherapy instituted using amphotericin B, flucytosine, or a combination of both yielded mixed results (Revankar et al. 2002). The advent of azole and echinocandin classes of drugs, however, has added to the available antifungal armamentarium. The so-called older azole drugs, such as itraconazole, are very effective against dematiaceous fungi in vitro (McGinnis and Pasarell 1998b; McGinnis et al. 1998). In one landmark study, nine of 17 patients with phaeohyphomycosis showed a marked positive response to itraconazole therapy (Sharkey et al. 1990). In addition, many of the newer azoles show good promise both in vitro (Espinel-Ingroff 1998a, b; McGinnis and Pasarell 1998a) and in vivo (Graybill et al. 2004; Negroni et al. 2004). In a mouse model of disseminated phaeohyphomycosis due to *W. dermatitidis*, posaconazole reduced tissue burden and prolonged survival. Additionally, posaconazole provided a complete cure to a woman with a 12-year case of relapsing phaeohyphomycosis due to *Exophiala spinifera* that disseminated upon pregnancy. Though small in number, these experiences suggest that therapeutic regimens employing azoles alone may be effective in the treatment of systemic phaeohyphomycosis.

Cerebral phaeohyphomycosis should be treated aggressively given the rather poor clinical outcome in both normal patients and those at risk (Filizzola et al. 2003; Perfect et al. 2003; Revankar et al. 2004). For single brain abscesses, surgical debridement may be essential for survival. Even partial removal may facilitate recovery, particularly when combined with antifungal therapy. When surgery is contraindicated, a concerted therapeutic approach must be taken. Yet, treatment failures occur even with high doses of amphotericin B and flucytosine. This may be due in part to the innate or acquired resistance of dematiaceous fungi to these drugs. As with disseminated phaeohyphomycosis, the newer azoles and echinocandins show great potential in treating cerebral infections. Murine models of cerebral phaeohyphomycosis due to either *R. obovoideum* (Al-Abdely et al. 2000) or *C. bantiana* (cited in Sanche et al. 2003) indicated that posaconazole was superior to amphotericin B and itraconazole in prolonging survival and reducing fungal counts in the brain. In addition, Trinh and colleagues (Trinh et al. 2003) recently reported that voriconazole and caspofungin markedly delayed the progression in a premature infant of a fatal cerebral infection caused by *C. bantiana*.

In summary, the treatment options for DSP are generally limited due to the efficacy of available antifungal agents and the limitations of surgical interventions. The newer antifungals, especially posaconazole, appear to hold promise for future advances in curing these infections. Perhaps a more concerted effort to clinically assess the azoles in the treatment of DSP needs to be undertaken, and in particular comparing the in vitro susceptibility of the different causative agents with patient outcome. It seems critical that such 'real world' data be collected and analyzed in order to determine if the promise of the newer antifungals will be fulfilled. In addition, another avenue ripe for exploration is immune modulation. A complete understanding of the immune response to DSP is lacking. More information in this area is needed before potential protocols can be established to enhance or target a host's immune system towards prohibiting and eliminating infections by dematiaceous fungi.

BIOLOGICAL ASPECTS RELATED TO PATHOGENESIS

Given the wide array of phylogenetically diverse fungi causing DSP, it is unlikely that there will be a great number of universal themes pertaining to the underlying molecular mechanisms responsible for virulence. In fact, as in most pathogenic fungi, virulence is not dependent upon one or two factors acting alone, but rather two or more modalities acting in conjunction with each other. Recent reviews have emphasized these same points (van Burik and Magee 2001; Cole 2003).

The dematiaceous fungi do, however, share a few common themes associated with virulence. These factors are best exemplified by *W. dermatitidis*, which can serve as a paradigm for most phaeoid fungi (Szaniszlo 2002). This fungus is polymorphic and is a cause of subcutaneous and deep-seated phaeohyphomycosis. Moreover, under the appropriate culture conditions, or through the use of particular morphological mutants, *W. dermatitidis* will produce muriform-like cells that resemble the 'sclerotic body' characteristic of chromoblastomycosis Hence, this fungus may serve as a model to study this disease as well. Two particular attributes of *W. dermatitidis* that contribute to virulence are briefly summarized below.

Perhaps one of the best-studied virulence factors in *W. dermatitidis* is melanin. The genetics and biochemistry of the pentaketide biosynthetic pathway leading to melanin production has been extensively characterized in this pathogen (Cooper and Szaniszlo 1997; Feng et al. 2001; Szaniszlo 2002). Prior to the cloning of a key gene in this pathway, melanin-deficient mutants of *W. dermatitidis* were shown to be significantly less virulent in a murine infection model than the pigment wild-type strain (Dixon et al. 1987b, 1989a, 1992). Subsequently, a genetically derived null mutant, defective in the gene encoding polyketide synthase (*WdPKS1*), was shown to be similarly less virulent (Feng et al. 2001). The proposed mechanism by which melanin functions in pathogenesis relates to experimental findings that this pigment acts as an antioxidant, thereby promoting survival of the oxidative bursts produced by phagocytes (Jacobson and Tinnell 1993; Schnitzler et al. 1999; Jacobson 2000). Melanin may also bind host hydrolytic enzymes that target the fungal plasma membrane. These experimental results have dramatic implications for other dematiaceous fungi given that melanin production in most of these species involves the same biochemical pathway (Wheeler and Bell 1988). Indeed, melanins have been shown to be important virulence factors in a phylogenetically diverse number of fungi pathogenic for humans, animals, and plants (Langfelder et al. 2003).

Chitin synthase represents another virulence factor in *W. dermatitidis* and, by extension, the phaeoid fungi in general. Chitin is a crucial cell-wall polymer that plays a significant role in the morphogenesis of nearly all fungi. This polysaccharide and the enzymes involved in its biosynthesis have been extensively studied in *W. dermatitidis* (Szaniszlo 2002). Null mutants were derived in five different chitin synthase genes. In addition, mutants bearing various combinations of these mutations were generated. Collectively, these mutations produced a wide range of morphological and growth phenotypes. When selected mutants were incubated at temperatures equivalent to that found in infection, cellular development was significantly altered or stopped. Moreover, certain mutants able to grow well at these temperatures and not exhibiting observable cellular abnormalities were less virulent than the wild-type strain in both immunocompetent and immunocompromised mouse models of infection (Wang et al. 1999, 2001; Liu et al. 2004). In short, chitin represents not only a target for the treatment of disease caused by *W. dermatitidis* and like fungi, but it also serves as yet another factor involved in pathogenesis.

SUMMARY AND FUTURE DIRECTIONS

DSP is characterized by the clinical presentation of disseminated and cerebral infections. Each has its own unique characteristics, although they share some similar histopathological features. They are both caused by a wide variety of fungal species having high levels of mortality even though most patients receive surgical and/or chemotherapeutic treatment. In the future, it is essential for medical mycologists, research scientists, and clinicians to make a concerted effort to develop additional intervention strategies employing newer antifungal agents that seem to show promise in early trials. Such strategies may focus upon the discovery of potential virulence factors and exploiting any unique fungus-specific features they present. Incorporated into these efforts should be the development of modern and more

efficient molecular diagnostics for DSP, although current skills in the more traditional areas of fungal culture and identification must be maintained as well as instilled in future generations of medical mycologists.

THE CONCEPT OF HYALOHYPHOMYCOSIS

Definition

The clinical nomenclature 'hyalohyphomycosis,' first used by Ajello (1982), serves as an umbrella term grouping together infections caused by molds that lack melanin in their cell walls (known as hyaline, non-dematiaceous or non-pheoid), which do not have other specific, well-established names, such as aspergillosis. This terminology allows for the inclusion of future non-melanized filamentous etiologic agents or disease states, thus avoiding the need to create a multitude of unnecessary names. Furthermore, it is resistant to the many taxonomic changes that inevitably happen (Matsumoto et al. 1994).

Causative organisms

Currently known agents of hyalohyphomycosis are many and varied, presently totaling more than 20 genera and 70 species (Table 1). Some of these species are well documented in causing disease (Table 2); others have been encountered less often.

The hyalohyphomycetes comprise a heterogeneous group characterized by production of colorless septate hyphae in host tissue. Hyphae are parallel-walled, typically showing irregular branching at both 45° and 90°. Hyphal diameter can vary substantially (2–8 μm), but is more slender than that of the Zygomycetes. Colony color can also differ widely, but is never darkly pigmented.

They are opportunistic pathogens, normally found as saprophytes in soil and vegetative matter, and frequently identified as plant pathogens. The most common agents of disease are species of *Fusarium*, *Scedosporium*, *Acremonium*, and *Paecilomyces*.

Identification of hyaline filamentous fungi is not always straightforward, and this chapter does not intend to provide an exhaustive text on the subject. Key characteristics of common genera are provided. However, the reader is referred to excellent guides on the identification of medically important species (Sutton et al. 1998; de Hoog et al. 2000; Larone 2002). Additional resources can be found at www.doctorfungus.org and www.clinicalmycology.com. Expert help may also prove advantageous.

Categories of disease

Hyaline hyphomycetes are capable of causing a wide spectrum of disease that can be further divided into superficial, deep tissue, and disseminated infections. This chapter aims to concentrate on deep-seated infection, and as such, does not give detail on other forms of disease, including those of the eye (see Oculomycosis).

Deep infections may involve the lungs, sinuses, heart, liver, spleen, kidney, bones, or central nervous system (Table 2), and are commonly acquired through the respiratory tract, gastrointestinal tract (e.g. after major surgery), or blood vessels (e.g. catheter-related). Skin breakdown or toenail onychomycosis can be the origin of infection in invasive fusarial disease (Boutati and Anaissie 1997). Major trauma may also result in

implantation. Infection can remain localized in deep tissue and organs, or can disseminate hematogenously or via the lymphatic system. Secondary dissemination to the skin is more frequently seen with some of the fungi described here than with disseminated aspergillosis.

Patients at risk

Recent advances in medical procedures, therapy, and education have been extremely successful in increasing survival in patients, whom, historically, would have had

limited treatment options and a poor prognosis. As a direct result, the incidence of infection with opportunistic fungal pathogens, such as hyaline molds, has increased substantially worldwide. Whilst overall a relatively small number of infections are encountered, associated mortality is disproportionately high. Persistent neutropenia is probably the key risk factor for infection with hyaline molds. Highly susceptible patients include those with underlying hematological malignancies, bone marrow transplant recipients, and solid organ transplantation. Interestingly, hyalohyphomycosis in individuals infected with the human immunodeficiency virus (HIV) appears to be relatively uncommon. HIV specifically targets the T-lymphocyte population whereas hyaline mold pathogens are primarily granulocyte-controlled infections (Matsumoto et al. 1994).

Immunocompetent individuals may also be infected by these pathogens. Common predisposing factors include near-drowning or penetrating trauma (Walsh et al. 2004).

DIAGNOSIS

Early diagnosis is important for a successful outcome in invasive hyalohyphomycosis; this, however, can be problematic. Such agents of disease are commonly encountered as laboratory contaminants. Furthermore, isolation of the fungus, particularly from respiratory tract sites, may simply represent colonization, which may or may not progress to infection depending primarily on the immunological status of the host and the virulence of the organism. Consequently, a positive culture from a nonsterile site, such as sputum, must be interpreted with caution. Nevertheless, since these infections can be rapidly devastating, isolation of the fungus must not be automatically dismissed without investigation, particularly in the immunosuppressed host. Definitive diagnosis requires the histological detection of hyphae in normally sterile body fluids and/or tissue sections, together with a positive culture whose morphology matches that seen by microscopy. However, biopsies may be contraindicated in some patients due to severe thrombocytopenia (Hennequin et al. 2002).

Microscopy

Direct microscopy may be helpful in preliminary diagnosis. It will rarely indicate which fungus is responsible, but should distinguish the zygomycetes and hyalohyphomycetes. The test is rapid and the diagnostic yield may be higher than culture alone (Denning et al. 2003). If both microscopy and culture are positive, the likelihood of invasive disease is much higher. Sputum, bronchial washings, and aspirates should be examined using 10 percent potassium hydroxide and Parker ink (1:1), Gram stain, or, preferably, a fluorescent chitin dye such as Calcofluor (to increase sensitivity). Body fluids and exudates should be concentrated by centrifugation and the sediment similarly examined microscopically.

Histology

Hyphae are difficult to detect in hematoxylin and eosin (H&E)-stained sections due to poor staining, and any delay waiting for the results of subsequent specialized fungal stains can have fatal consequences. Therefore, tissue biopsies should be stained with a fungal stain in parallel with standard stains. Periodic acid–Schiff (where cell walls will be red) or a silver stain such as Gomori methenamine silver or Grocott stain (which will stain cell walls black) is recommended. Absence of melanin in the cell wall can usually be confirmed with a melanin stain such as the Fontana–Masson stain, although unstained or H&E-stained specimens should reveal melanin pigment, if present. In histological preparations, it can be almost impossible to distinguish between the various genera of hyaline molds, and agents of hyalohyphomycosis may be misidentified as *Aspergillus* spp. Moreover, histological appearance of fungi may be altered after antifungal therapy (Walts 2001; Denning et al. 2003). Immunohistological staining and in situ hybridization have both been used on tissue sections to differentiate *Fusarium* and *Scedosporium* spp. from other hyalohyphomycetes, including *Aspergillus* spp. However, antibodies to hyaline hyphomycetes, other than *Aspergillus*, are not commercially available (Kaufman et al. 1997; Hayden et al. 2003).

Culture

Since direct microscopy or histopathology may not be reliable means of distinguishing between the various genera of hyaline molds, all specimens should be cultured using a primary isolation medium, such as Sabouraud glucose agar. Cycloheximide should be avoided since many fungal species are sensitive to this compound. Furthermore, prior antifungal therapy could reduce the yield or sensitivity of culture. On occasion, isolates may appear colonially atypical or fail to sporulate on primary isolation media. Subculturing on to less nutritionally rich agars, such as half-strength cornmeal or potato dextrose agar, may help induce sporulation. Some organisms grow rather slowly; therefore, it would be prudent to incubate cultures for 4–6 weeks, generally at 30°C.

Definitive identification of the etiologic agent can then be accomplished using macroscopic and microscopic morphology. Identification is crucial for guiding antifungal therapy since intrinsic resistance to one or more drugs has been noted in many genera (Table 3). Acquired resistance is less well characterized. The National Committee for Clinical Laboratory Standards (NCCLS)(National Committee for Clinical Laboratory

a) Generally regarded as dematiaceous; included to enable comparison between species.

Standards 2002) has developed a standardized method, M38-A, for susceptibility testing of these organisms. The E-test method (AB Biodisk, Sweden) has also been investigated, achieving 70–100 percent agreement depending on drug and organism, with the M38 method (Pfaller et al. 2000; Espinel-Ingroff 2001). However, due to the relative infrequency of such organisms, these tests are unlikely to be clinically validated for some time. Such testing should be performed by a specialist laboratory.

Other tests

In contrast to other mold infections, including aspergillosis, *Fusarium*, *Scedosporium*, *Acremonium*, and *Paecilomyces* can be isolated relatively easily from routine blood cultures. This is most likely due to the expression of unicellular structures in infected tissues (adventitious forms), which are thought to facilitate hematological dissemination more easily than hyphal elements (Boutati and Anaissie 1997; Pontón et al. 2000). Furthermore, use of a specific fungal medium may provide a reduction in detection time compared to standard aerobic medium (Hennequin et al. 2002).

To date, no commercially available serologically based methods are available to aid in the diagnosis of any specific hyalohyphomycosis. Assays exist for the detection of 1,3-β-D-glucan, a component of most fungal cell walls, including the hyaline molds. Whilst these may be useful in diagnosis of fungal infection, they are unable to distinguish between different fungal genera (Obayashi et al. 1995). A number of molecular tests, generally polymerase chain reaction (PCR)-based, have been developed both for diagnosis of systemic mycoses from clinical samples, and for identification of fungal cultures, including *Fusarium* and *Scedosporium* spp. (Hue et al. 1999; Chen et al. 2002; Pryce et al. 2003).

PREVENTION

Nosocomial hyalohyphomycete infections have been reported. Potential reservoirs include hospital water supplies, soil of potted plants, and nearby landscaping or construction work. Contaminated drinking water or foodstuffs such as nuts and spices may also be hazardous (Summerbell et al. 1989; Berenguer et al. 1997; Anaissie et al. 2001; Shaw 2002; Dignani and Anaissie 2004). Of particular note, *Paecilomyces* spp. are resistant to standard sterilization methods and outbreaks have been associated with contaminated skin lotion (Orth et al. 1996). Every attempt should be made to ensure immunocompromised patients avoid exposure to potential environmental sources.

Fluconazole prophylaxis is routinely used in immunocompromised patients, especially bone marrow transplant recipients, and has been successful in reducing the frequency of *Candida* infections. However, a higher prevalence of mold infections at autopsy has been recorded in marrow transplant patients, possibly due to increased early post-transplantation survival (van Burik et al. 1998). Moreover, empirical treatment in febrile neutropenic patients is now generally regarded as accepted practice since therapeutic delay can result in increased morbidity and mortality. The drug of choice is usually amphotericin B. Many agents of hyalohyphomycosis are clinically resistant to this agent (Table 3), and invasive infection may develop regardless of therapy (Merz et al. 1988). Consequently, a high index of suspicion should be maintained amongst neutropenic patients receiving antifungal prophylaxis or empiric therapy.

PRINCIPAL HYALINE MOLDS CAUSING DEEP INFECTIONS

Fusarium species

BRIEF DESCRIPTION OF THE GENUS

Members of the genus *Fusarium* are anamorphic (asexual) filamentous organisms that propagate by producing conidia (asexual spores). Sexual states (teleomorphs) have been described in some of the fusaria.

Conidiogenous cells (termed phialides) are formed on aerial septate hyphae or short, branched conidiophores that are often in dense clusters (sporodochia). Microconidia and macroconidia are typically produced, although microconidia may be absent in some species. Some species also contain blastoconidia. In addition, hyaline or pale chlamydospores, produced intercalary or terminally, singly or in chains, may be seen in some species. In comparison to plant-dwelling strains, clinical isolates often exhibit a reduced morphology.

MORPHOLOGY

For the majority of species, colonies grow rapidly (40–80 mm within 7–10 days) although some species such as *Fusarium dimerum* are rather slower growing (less than 20 mm in 7–10 days). Initially colonies may be white but darken with age to shades of cream, purple, pink, red, or yellow (Figure 1). Similarly, the reverse may be pale but can darken to purple, red, green, blue, or brown as the culture matures. Sporodochia may not always be seen in culture. If present, they are often cream, orange, or tan. Colony texture can vary, but is usually floccose, woolly, or cottony.

Large smooth sickle- or canoe-shaped macroconidia (5–73×1.5–6 μm) with one to five transverse septa (Figure 1) are produced in basipetal fashion (growing from the base) from monophialides or sporodochia, accumulating in slimy masses. These conidia are thick-walled with a basal foot cell and an often pointed apical end. Macroconidia, typically used in identifying the genus and species, may only be apparent in the later stages of growth; thus care must be taken not to confuse young cultures, where only microconidia are evident, with *Acremonium* spp.

Microconidia are produced also in basipetal series on mono- or polyphialides, accumulating in small slimy heads or, sometimes, chains (Figure 1). They are generally unicellular, although two- or three-celled varieties are occasionally observed, and variable in size and shape (4–26×1.5–11 μm, smooth, oval, subspherical or pyriform, straight or curved with a rounded or flat base) (Nelson et al. 1994; Sutton et al. 1998; de Hoog et al. 2000).

Molecular methods, such as 28S rRNA gene sequencing, have been used to identify *Fusarium* spp. (Hennequin et al. 1999).

EPIDEMIOLOGY

Fusarium spp. are frequently found as saprophytes on organic debris and in soil. They are commonly implicated as plant pathogens, and indeed may cause economically devastating disease. Conversely, *Fusarium venenatum* (previously misidentified as *Fusarium graminearum*) is a commercially useful organism, being used for mycoprotein production for human consumption (Quorn).

Some species are more commonly found in tropical or temperate climates, whilst others are more geographically widespread, including desert and arctic areas. Despite worldwide distribution, most cases of invasive fusariosis have been reported from the United States and Southern Europe, particularly France. Moreover, *Fusarium* spp. are more abundant in the air during the rainy summer–autumn months, coinciding with increased infection rates (Nelson et al. 1994; Boutati and Anaissie 1997; Girmenia et al. 2000).

More than 50 species of *Fusarium* have been described, the taxonomy of which is confusing and under revision. Only a small number of species, however, have been docu-

mented as causing human infection (Table 1). The most virulent appears to be *Fusarium solani*, which, not surprisingly, is also most commonly isolated (in approximately 50 percent of cases). *Fusarium oxysporum* and *Fusarium verticillioides* (*moniliforme*) are also commonly encountered. Other rarer species include *Fusarium proliferatum* and *F. dimerum* (Mayayo et al. 1999; Pontón et al. 2000).

Fusarium spp. are the most common cause of fungal keratitis and were previously considered to cause only corneal, skin, and nail infections (not discussed in this chapter). However, they are now recognized as having the ability to cause disseminated disease and, indeed, in some centers, have emerged as the most common non-*Aspergillus* mold pathogen (Anaissie et al. 1988; Marr et al. 2002). Disseminated fusarial infection was first described in 1973 in a child with acute leukemia (Cho et al. 1973). One US institution recorded a significant increase from 0.5 to 3.8 cases per year from 1975 to 1995 (Boutati and Anaissie 1997). Incidence rates in other centers worldwide have remained more stable (5.1 and 6.3 mean cases per year for the periods 1981–90 and 1991–96, respectively) (Girmenia et al. 2000).

Fusarium spp. are able to produce several mycotoxins. Alimentary toxic aleukia is one of the most important mycotoxicoses. During the 1930s to 1950s, this disease was widespread in Siberia due to overwintering cereal grains on the field. Upon ingestion of contaminated food, mycotoxins cause tissue breakdown and suppress cellular and humoral immunity, resulting in bone marrow failure and potentially fatal disease (Nelson et al. 1994). It is currently unknown whether such toxins are expressed in human tissue during disseminated infection. Adherence factors may also be important in catheter-related infections (Pontón et al. 2000; Dignani and Anaissie 2004).

RISK FACTORS AND CLINICAL MANIFESTATIONS

Fusarium spp. have been documented as causing infections in almost any organ, including mycetoma, keratitis, pulmonary infections, endocarditis, catheter infections, brain abscess, and fungemia (Table 2).
Skin and soft tissue infections may be indolent, locally invasive, or manifestations of systemic disease. Toenail onychomycosis and skin lesions can both be a source of dissemination in immunosuppressed individuals; thus a thorough skin and nail examination should be performed in patients prior to commencement of immunosuppressive therapy. Endogenous endophthalmitis may also be an indication of disseminated infection (Castagnola et al. 1993; Velasco et al. 1995; Boutati and Anaissie 1997; Camin et al. 1999; Nucci et al. 2003).

Deep infections within the immunocompetent patient setting usually remain localized, and include continuous ambulatory peritoneal dialysis (CAPD)-associated peritonitis, or septic arthritis and osteomyelitis, generally as a result of trauma or surgery. Disseminated infection has occurred rarely in immunocompetent patients; risk factors include those with extensive burns (Guarro and Gené 1995; Dignani and Anaissie 2004).

Risk factors for invasive disease include persistent neutropenia and graft-versus-host disease (GVHD) (Walsh et al. 2004). Patients with underlying hematological malignancies are most susceptible, with more than 90 percent of reported cases of fusariosis occurring in this population, half of which were acute leukemic patients (Pontón et al. 2000). Hematopoietic stem cell transplant recipients may be at particular risk, especially those who have received grafts with human leukocyte antigen-mismatched or unrelated donors or have undergone multiple transplants (Marr et al. 2002; Nucci 2003). Fusarial infection in solid organ transplant recipients appears to be less prevalent, with only eight cases reported until 2003, five in renal transplant recipients (Nucci 2003).

Invasive disease initially presents as persistent fever (>90 percent) refractory to broad-spectrum antibiotics (and perhaps also to antifungal drugs) in a profoundly neutropenic patient, possibly with pulmonary infiltrates and/or sinusitis (70–80 percent), similar to invasive aspergillosis. However, unlike aspergillosis (<10 percent of cases), metastatic cutaneous lesions may be seen in 70–90 percent of cases, sometimes preceding fungemia (1–10 days). Moreover, skin lesions are characteristic, evolving from subcutaneous nodules to erythematous lesions, later becoming necrotic, and may provide the sole diagnostic sign in >50 percent of patients. In further contrast to aspergillosis, routine blood cultures are positive in 40–60 percent of cases. Antemortem diagnosis is achieved in >90 percent of cases (Merz et al. 1988; Martino et al. 1994; Boutati and Anaissie 1997; Nucci and Anaissie 2002; Dignani and Anaissie 2004).

TREATMENT AND PROGNOSIS

In patients with catheter-associated infection, such as those with CAPD peritonitis, catheter removal is required, in addition to systemic antifungal treatment. Localized infection in the solid organ transplant recipient may respond to surgical resection, together with long-term antifungal therapy. Favorable response rates may be achieved with such localized infections. Nonetheless, timely treatment is crucial if disseminated infection is to be avoided (Velasco et al. 1995).

The overall mortality rate associated with invasive fusarial infection remains very high (52–70 percent). Persistent neutropenia and corticosteroid administration are significant prognostic factors. In those who do not recover from neutropenia, the death rate will be almost 100 percent, despite antifungal therapy. Attributable mortality in solid organ transplant recipients with fusariosis appears to be lower, possibly because

these infections tend to be more localized (Groll and Walsh 2001; Nucci et al. 2003; Dignani and Anaissie 2004).

Optimal therapy has yet to be established. Since outcome is poor unless the neutrophil count increases, efforts to modulate the host response by administration of growth factor [granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF)] and/or colony-stimulating factor (CSF)-stimulated granulocyte transfusion and, if possible, concomitant reduction of immune suppressive therapy may be beneficial (Spielberger et al. 1993; Boutati and Anaissie 1997; Hennequin et al. 1997).

Fusarium spp., particularly *F. solani*, are resistant to most of the established antifungal drugs (Table 3). Amphotericin B shows some activity in vitro, although in vivo data may be contradictory (Pujol et al. 1997; Arikan et al. 1999; Guarro et al. 1999; Ortoneda et al. 2002a). Nevertheless, satisfactory response, or at least control of the infection allowing recovery of immune function, may sometimes be achieved with high doses of conventional or, preferably, liposomal amphotericin B (Boutati and Anaissie 1997; Letscher-Bru et al. 2002).

Voriconazole has also been used to effectively treat invasive *Fusarium* infection, and recently was approved for such indications (Consigny et al. 2003; Vincent et al. 2003). This efficacy is supported by in vitro and in vivo data, although *F. solani* may be less susceptible (Clancy and Nguyen 1998; Arikan et al. 1999; Paphitou et al. 2002; Graybill et al. 2003).

Posaconazole shows modest in vitro and in vivo activity (Lozano-Chiu et al. 1999; Paphitou et al. 2002), whilst *Fusarium* spp. are intrinsically resistant to echinocandin agents (Pfaller et al. 1998; Tawara et al. 2000; Arikan et al. 2001).

Combination therapy, often amphotericin B with an azole agent, has shown promising activity in vitro and has been used clinically with some degree of success (Durand-Joly et al. 2003; Ortoneda et al. 2004).

Scedosporium species

BRIEF DESCRIPTION OF THE GENUS

The genus *Scedosporium* contains two medically important species, *Scedosporium apiospermum* and *Scedosporium prolificans*. *S. prolificans* (formerly *Scedosporium inflatum*) is regarded as dematiaceous (darkly pigmented), but has been included within this chapter to ease comparison between the two species.

S. apiospermum is the asexual state of teleomorph *Pseudallescheria boydii*, which is homothallic (sexual reproduction requiring only a single organism). The synanamorph *Graphium eumorphum* may also exist in some strains.

The sexual form of *S. prolificans* has been described as belonging to the genus *Petriella*.

MORPHOLOGY

Colonies of *S. apiospermum* spread rapidly (40 mm within 7–10 days), initially white but becoming dark gray or brown, with a hairy, woolly, or cottony texture (Figure 2). A pale reverse is initially seen, developing brown or black areas.

The teleomorph *P. boydii* produces spherical brown fruiting bodies, 140–200 μm in diameter, known as cleistothecia, which contain asci and ascospores. However, it is rare for clinical strains to produce these sexual structures; prolonged incubation may be required to induce their formation. In the asexual form, cylindrical conidiogenous cells (termed annellides) arise from branching septate hyphae (2–4 μm in diameter) and produce slimy masses of conidia. Conidia (6–12×3.5–6 μm) are unicellular, smooth, and oval with a flat base, initially colorless or pale becoming brown and thick walled. Conidia are sometimes produced directly on the hyphae (sessile). In the *Graphium* state, conidiophores are sometimes bundled together, forming synnemata, producing clusters of conidia at their apical tip (Figure 2). Both asexual forms may exist in a single isolate.

Colonies of *S. prolificans* also grow rapidly (20 mm within 7–10 days), initially with a moist, almost yeast-like texture, later developing tufts of aerial hyphae. The

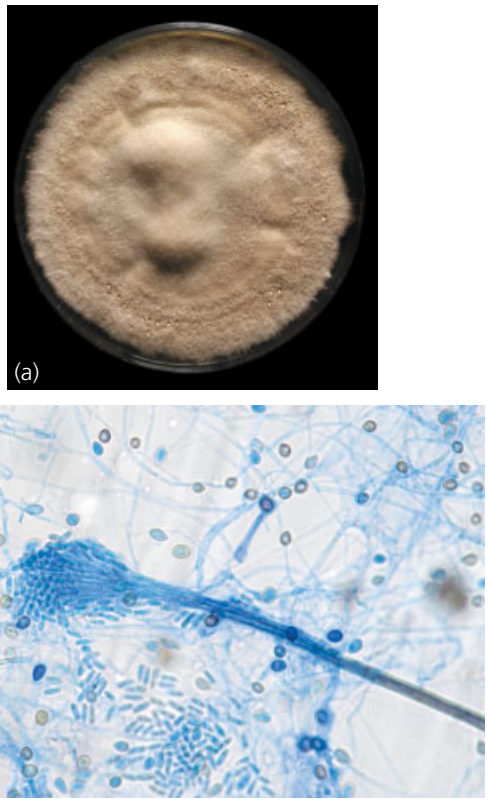

Figure 2 (a) *Culture of* Scedosporium apiospermum *(Sabouraud glucose agar, 30°C, 14 days) and* **(b)** *microscopic appearance showing synnemata (*Graphium *state). © Salford Royal Hospitals NHS Trust*

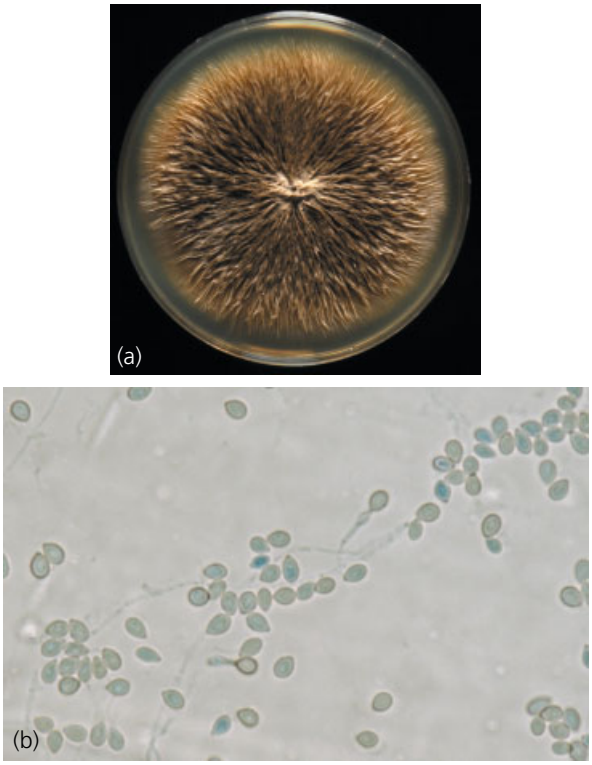

Figure 3 (a) *Culture of* Scedosporium prolificans *(Sabouraud glucose agar, 30°C, 14 days) and* **(b)** *microscopic appearance.* *© Salford Royal Hospitals NHS Trust*

colony color may be olive-gray or black with a gray to black reverse, more darkly pigmented than that of *S. apiospermum* (Figure 3).

Conidiogenous cells of *S. prolificans* are characteristically flask-shaped with an inflated base, often with an elongated tip (Figure 3). Single-celled, smooth, oval, flat-based, olive-brown conidia (3–7×2.5 μm) accumulate in slimy heads. Sessile conidia, which are darker and rounder, may also be seen (de Hoog et al. 2000).

S. apiospermum and *S. prolificans* also differ in their physiology: unlike *S. prolificans*, *S. apiospermum* is able to assimilate ribitol, xylitol, and L-arabinitol. Furthermore, *S. apiospermum* can grow on cycloheximide-containing media (e.g. Mycosel), whereas *S. prolificans* is inhibited by the compound. Molecular methods have also been used to discriminate between the two species (Wedde et al. 1998).

EPIDEMIOLOGY

Scedosporium spp. occur worldwide. *S. apiospermum* is frequently found as a saprophyte in soil, sewage, manure, and contaminated water. The natural habitat of *S. prolificans* appears to be soil, while it has been isolated from the hospital environment during building works. Both species have historically been important causes of subcutaneous infection in immunocompetent individuals (not discussed here), normally following minor trauma such as splinters or thorns. They are, however, becoming increasingly implicated in invasive disease. In vivo work suggests that *S. prolificans* is more virulent than *S. apiospermum*. Interestingly, most cases of disseminated *S. prolificans* infection have been recorded in Spain and Australia; the reasons for this distribution remain unclear (Cano et al. 1992; Berenguer et al. 1997; Bouza and Muñoz 2004).

RISK FACTORS AND CLINICAL MANIFESTATIONS

Scedosporium infection may involve almost any organ (Table 2). Reports of *S. apiospermum* infection include invasive pulmonary disease, sinusitis, brain abscess, endocarditis, fungemia, mycetoma, and peritonitis (Jabado et al. 1998; Nesky et al. 2000; Castiglioni et al. 2002; Raj and Frost 2002; Bouza and Muñoz 2004). *S. prolificans* has also caused renal and splenic abscess, in addition to pulmonary infections, endocarditis, fungemia, and many other manifestations (Marin et al. 1991; Carreter de Granda et al. 2001; Simarro et al. 2001; Bouza and Muñoz 2004).

For both species, manifestations in immunocompetent individuals are usually localized, and include subcutaneous infections, septic arthritis, osteomyelitis, and sinusitis. Pulmonary infection and endocarditis in the normal host have also been reported (Sobottka et al. 1999; Greig et al. 2001; Tirado-Miranda et al. 2001; Levine et al. 2002). The main risk factors are surgery or trauma, although intravenous drug use has also been reported as such (Berenguer et al. 1997; Bouza and Muñoz 2004). *S. apiospermum* has caused fatal pulmonary, cerebral, and disseminated infection in near-drowning victims in polluted water and sewage (Dworzack et al. 1989). In addition, either species may colonize the airway of cystic fibrosis patients, triggering allergic disease in some (Cimon et al. 2000).

Patients at high risk of disseminated disease include those receiving corticosteroids or with prolonged neutropenia. Indeed, at least 90 percent of cases are associated with persistent neutropenia. Those with hematological malignancy, particularly acute leukemia, or hematopoietic stem cell transplant recipients are especially at risk (Berenguer et al. 1997; Revankar et al. 2002). The incidence of *S. apiospermum* infection in solid organ transplant recipients is approximately 0.1 percent, with lung transplant recipients most at risk (Castiglioni et al. 2002).

Clinical signs of invasive infection are typically similar to those produced by *Aspergillus* or *Fusarium*: unremitting fever (>90 percent) unresponsive to broad-spectrum antibiotics (and possibly also to antifungal agents) in a persistently neutropenic patient, followed by pulmonary involvement (approximately 75 percent). Indeed, with both *Scedosporium* spp. the lung is the most common site of infection in immunocompromised patients. Frequent dissemination to other organs is seen, with a particular propensity for the central nervous system.

Neurological symptoms may be noted (approximately 30–40 percent for *S. prolificans*, possibly even higher with *S. apiospermum*), in addition to widespread metastatic cutaneous lesions (25 percent), which typically appear as nodules, possibly becoming necrotic. Metastatic eye involvement may also occur (approximately 10 percent). Dissemination is often seen in solid organ transplant patients, in contrast to fusarial infection in such patients (Berenguer et al. 1997; Bouza and Muñoz 2004). Positive blood cultures are obtained in approximately 80 percent of *S. prolificans* infections (Revankar et al. 2002), whereas the isolation rate is much lower for *S. apiospermum*. Occasional case reports suggest that indwelling central venous catheters may also serve as a portal of entry, particularly with *S. prolificans* (Berenguer et al. 1997).

TREATMENT AND PROGNOSIS

Successful outcomes are often achieved in immunocompetent patients since disease tends to be more localized. A maximal dose of antifungal treatment in combination with surgical debridement and/or drainage, if appropriate, is usually the therapy of choice (Wood et al. 1992; Berenguer et al. 1997).

On the contrary, in the immunocompromised host, *Scedosporium* usually results in a rapidly disseminated infection that is almost universally lethal (85–100 percent) (Wood et al. 1992; Berenguer et al. 1997; Castiglioni et al. 2002; Marr et al. 2002; Revankar et al. 2002). These data indicate that resolution of neutropenia is absolutely crucial for survival, particularly since these organisms are resistant to many antifungal drugs (Table 3).

Therapeutic choices are very limited. As with *Fusarium* infections, administration of hematopoietic growth factors may help with neutropenic resolution. Immunosuppressants should also be reduced if clinically justifiable (Idigoras et al. 2001).

S. prolificans is intrinsically resistant to amphotericin B. Most *S. apiospermum* isolates are resistant in vitro and treatment failures have been widely reported (Ellis 2002; Meletiadis et al. 2002). Indeed, *Scedosporium* infection can often develop during amphotericin B treatment (Berenguer et al. 1997; Safdar et al. 2002). Interestingly, in vitro studies have shown that antifungal drugs, including amphotericin B, cooperate with polymorphonuclear leukocytes to cause increased damage to *Scedosporium* hyphae (Gil-Lamaignere et al. 2002). Moreover, combination therapy of liposomal amphotericin B and G-CSF prolonged survival in an in vivo disseminated *S. prolificans* model (Ortoneda et al. 2002b).

Itraconazole and miconazole both show some activity in vitro and have been used clinically with some degree of success against *S. apiospermum*, but rarely so with *S. prolificans* infections. Intravenous miconazole, however, has toxic side effects (Nomdedeu et al. 1993; Cuenca-Estrella et al. 1999; Meletiadis et al. 2002; Bouza and Muñoz 2004).

Voriconazole was recently indicated for *Scedosporium* infections, and numerous case studies have demonstrated efficacy against *S. apiospermum* (Girmenia et al. 1998; Muñoz et al. 2000; Nesky et al. 2000; Poza et al. 2000). In vitro data confirm activity against *S. apiospermum*, and to a lesser extent, *S. prolificans* (Cuenca-Estrella et al. 1999; Carrillo and Guarro 2001).

Posaconazole activity against *S. prolificans* is poor. However, in vitro and in vivo responses against *S. apiospermum* have been noted (Espinel-Ingroff 1998; Carrillo and Guarro 2001; Meletiadis et al. 2002; González et al. 2003). In addition, Mellinghoff et al. (2002) report successful posaconazole treatment of *S. apiospermum* brain abscesses in a leukemic patient, after failure of itraconazole, amphotericin B, and ketoconazole.

S. apiospermum and *S. prolificans* appear moderately susceptible in vitro to the echinocandin agents, but no clinical data exist (Espinel-Ingroff 1998; Uchida et al. 2000).

Combination antifungal therapy may provide additional therapeutic options. Voriconazole in combination with terbinafine has been used successfully to treat disseminated *S. prolificans* infection (Howden et al. 2003). In vitro studies confirm synergy with azole/terbinafine combinations (Meletiadis et al. 2003). In addition, liposomal amphotericin B combined with itraconazole produced a favorable outcome in *S. apiospermum* infection, but not *S. prolificans* (Barbaric and Shaw 2001).

Other species

Many other species, particularly *Acremonium*, *Paecilomyces*, and *Scopulariopsis*, have been documented rarely as causing deep tissue or disseminated infection (Table 1).

MORPHOLOGY

The growth rate of *Acremonium* spp. is moderate (10–30 mm in 7 days), generally slower than *Fusarium* spp. Colonies are flat, occasionally raised in the center, glabrous to velvety and may be pink, yellow, or white with a colorless, pinkish, or pale brown reverse. Microconidia (3–10×1.5–3 μm) accumulate at the tips of narrow tapering phialides (de Hoog et al. 2000).

Paecilomyces spp. grow rapidly (30–50 mm in 7 days), initially white, becoming brownish or violet, with a powdery to floccose texture. Conidiophores with characteristic tapering phialides and chains of conidia are observed (de Hoog et al. 2000).

Colonies of *Scopulariopsis* spp. are typically white, becoming light or dark brown, with a cream to brown reverse. They grow moderately quickly (30 mm in 7 days) with a powdery to velvety texture. Conidiophores,

annellides, and often rough-walled conidia arranged in chains are seen (de Hoog et al. 2000).

EPIDEMIOLOGY

Acremonium, *Paecilomyces*, and *Scopulariopsis* spp. inhabit soil and plant material; some species of the latter two can also be isolated from insects. All three genera occur worldwide. They may be encountered as contaminants, but are also capable of causing infection, especially in the immunocompromised host.

Each genus contains a number of species, although only a few have been reported as human pathogens (Table 1). Most *Acremonium* infections have been caused by *Acremonium kiliense* or *A. strictum*. Other species include *Acremonium alabamense*, *Acremonium falciforme*, and *Acremonium recifei*. There are two medically prevalent species of *Paecilomyces*, *Paecilomyces lilacinus* and *Paecilomyces variotii*. Other species include *Paecilomyces javanicus* and *Paecilomyces marquandii*. *Scopulariopsis* infections are primarily caused by *Scopulariopsis brevicaulis*, although other species have been noted, including *Scopulariopsis acremonium*, and *Scopulariopsis candida* (Herbrecht et al. 2002; Steinbach et al. 2004; Walsh et al. 2004).

RISK FACTORS AND CLINICAL MANIFESTATIONS

Acremonium, *Paecilomyces*, and *Scopulariopsis* spp. have been documented as causing a wide spectrum of disease (Table 2).

In the immunocompetent patient, ocular infection (not discussed in this chapter) is the main clinical manifestation of *Acremonium* and *Paecilomyces* spp., typically following traumatic or surgical injury. *Acremonium* is one of the main causative agents of mycetoma, whereas the most common presentation of *Scopulariopsis* infection is onychomycosis, generally of the toenail (neither discussed) (Guarro et al. 1997; Chan-Tack et al. 1999; Steinbach et al. 2004). Nonetheless, *Acremonium* and *Paecilomyces* have been reported as causing peritonitis, endocarditis, and sinusitis (Guarro et al. 1997; Heitmann et al. 1997; Aguilar et al. 1998; Kovac et al. 1998; Nayak et al. 2000; Manzano-Gayosso et al. 2003). Endocarditis caused by *Scopulariopsis* has also been documented (Chen-Scarabelli and Scarabelli 2003).

In the immunocompromised individual, the spectrum of disease includes fungemia and pulmonary and cerebral infections (Boltansky et al. 1984; Guarro et al. 1997; Sillevis Smitt et al. 1997; Sellier et al. 2000; Nedret Koç et al. 2002; Kantarcioğlu et al. 2003; Steinbach et al. 2004).

Similar to *Fusarium* and *Scedosporium* spp., predisposing factors for such invasive disease includes persistent neutropenia and corticosteroid use. Hematopoietic stem cell and organ transplant recipients are most at risk (Guarro et al. 1997; Steinbach et al. 2004; Walsh et al. 2004). Furthermore, clinical presentation is also comparable to other invasive hyalohyphomycoses. Cutaneous lesions may be the first indication of infection, although blood cultures are often positive during *Acremonium* and *Paecilomyces* infections (Guarro et al. 1997; Pontón et al. 2000; Steinbach et al. 2004).

TREATMENT AND PROGNOSIS

Since these infections occur rarely, few clinical data exist to confirm optimal treatment. Localized infection may be resolved by surgery and antifungal therapy. On the contrary, complete recovery from disseminated infection depends almost entirely on recovery of the neutrophil count. Choice of antifungal drug effective against these agents is limited (Table 3); hence combination therapy has generally been utilized.

Amphotericin B, often in combination with an azole, has typically been used against *Acremonium* infection. In vitro activity is seen with some isolates, although clinical response is variable. Higher doses may improve the success rate (Guarro et al. 1997; Groll and Walsh 2001). Voriconazole and posaconazole are active in vitro against some species. More importantly, clinical successes have been reported in patients with hematological malignancies who had failed amphotericin B therapy (Herbrecht et al. 2002; Mattei et al. 2003). Of the limited in vitro data available, caspofungin appears active against *Acremonium* spp., though no clinical data exist (Espinel-Ingroff 1998; Pfaller et al. 1998).

Species identification of *Paecilomyces* is important due to variations in antifungal susceptibility (Table 3). *P. lilacinus* is resistant in vitro to amphotericin B and itraconazole, whilst *P. variotii* is susceptible (Radford et al. 1997; Aguilar et al. 1998; Espinel-Ingroff et al. 2001). Amphotericin B, either alone or in combination with other agents, has been the most widely used regimen against *Paecilomyces* infections. However, a 40 percent failure rate is seen (Aguilar et al. 1998). Voriconazole and posaconazole are active in vitro against some *Paecilomyces* spp. (Radford et al. 1997; Wildfeuer et al. 1998; Espinel-Ingroff et al. 2001; Uchida et al. 2001). Furthermore, voriconazole has been used with partial success against *P. lilacinus* skin and soft tissue infections in immunocompromised individuals who had failed amphotericin B and/or itraconazole therapy (Hilmarsdóttir et al. 2000; Martin et al. 2002). Caspofungin appears active in vitro against *P. variotii*, although *P. lilacinus* is resistant (Del Poeta et al. 1997). Interestingly, caspofungin in combination with itraconazole was used successfully against progressive cutaneous *P. lilacinus* infection (Safdar 2002). Micafungin shows good activity in vitro against both *P. variotii* and *P. lilacinus*, although this has not been substantiated clinically (Uchida et al. 2000). Terbinafine has been used successfully in a soft tissue infection caused by *P. lilacinus* in a heart transplant recipient (Clark 1999).

Historically, amphotericin B has been the therapy of choice in invasive *Scopulariopsis* infections, but is often

ineffective (approximately 60 percent), correlating with in vitro resistance (Aguilar et al. 1999; Steinbach et al. 2004). Itraconazole also shows poor in vitro activity, although a few case studies report success (Radford et al. 1997; Espinel-Ingroff et al. 2001; Steinbach et al. 2004). Variable in vitro responses to voriconazole and clinical failure of voriconazole combined with caspofungin have been reported (Wildfeuer et al. 1998; Espinel-Ingroff et al. 2001; Cuenca-Estrella et al. 2003; Steinbach et al. 2004). In vitro and clinical response to caspofungin was documented against *Scopulariopsis* endocarditis (Chen-Scarabelli and Scarabelli 2003). Recurrent subcutaneous infection caused by *S. brevicaulis* in a liver transplant recipient was controlled with surgery and long-term terbinafine therapy (Sellier et al. 2000).

A NOTE ABOUT NOMENCLATURE

Since the publication of the previous (9th) edition of this book in 1998, distinct species within the genus *Pneumocystis* have been described. The species which infects human beings was described as *Pneumocystis jirovecii*, while *Pneumocystis carinii* was retained as the name of the species first identified in rats (Frenkel 1999). The species infecting mice was named *Pneumocystis murina* (Keely et al. 2004) and another species found in rats was given the binomial, *Pneumocystis wakefieldiae* (Cushion et al. 2004a). *P. jirovecii* as the name for the human species is controversial (Stringer et al. 2002, 2003; Hughes 2003) and its validity will be decided by the International Botanical Congress in 2005. In this chapter, *Pneumocystis carinii* is used in the section on History below to refer to organisms from any host. Throughout the remaining sections, care is taken to use the correct species assignations when known. The term '*Pneumocystis*' is used when referring to the organisms in general or when the host of origin is not known.

HISTORY

Pneumocystis carinii was first described in Brazil by Carlos Chagas in 1909, while studying infections with *Trypanosoma cruzi* in humans and animal models (Chagas 1909). He interpreted sickle and rounded forms within cyst forms of the organism as male and female stages of trypanosoma. An Italian investigator who agreed with this description, Antonio Carini, sent slides from the lungs of rats infected by *Trypanosoma lewisi* to associates in Paris. Dr and Mrs Delanoë at the Pasteur Institute reviewed the slides and proved conclusively in 1912 that the organism was not a trypanosome, but an entirely different species of protozoan parasite (Delanoë and Delanoë 1912). Since the original diagnostic slides were contributed by Dr Carini, the organism species name bore his surname while the genus recognized both the tropism for the lung (pneumo-) and the characteristic developmental form (-cyst) of the microbe.

Throughout the next three decades, little notice was paid to these organisms, although their presence was observed in the lungs of several mammalian species. Epidemics of the pneumonia were first reported in the 1940s and were especially virulent in European orphanages that housed poorly nourished and sickly children in crowded conditions following World War II (Gajdusek 1957). The pneumonia was characterized by a prominent plasma cell infiltrate in the lung interstitium and the presence of an alveolar exudate described as 'honeycombed' upon histological examination. In 1942, van der Meer and Brug unambiguously reported the presence of the organisms in the lungs of humans (van der Meer and Brug 1942). In 1951, Vanek established the etiologic agent of interstitial plasma cell pneumonia as *Pneumocystis* by demonstration of the organisms in alveolar exudate of children dying of the pneumonia (Vanek 1951). By 1955, the first cases of infection were reported in the USA, although the American

pediatricians were reluctant to accept the etiologic agent as *Pneumocystis* (Gajdusek 1957).

Improved conditions associated with economic recovery in Europe led to a decline in cases of the pneumonia by the 1960s. In 1958, Ivady and Paldy reported the successful treatment of infants with interstitial plasma cell pneumonia (Ivady and Paldy 1958). Previously, this family of cationic diamidine compounds was routinely used for therapy of African trypanosomiasis, or 'sleeping sickness.' This drug became generally accepted as the treatment of choice for *Pneumocystis* pneumonia until the 1970s when it was supplanted by the less toxic and highly efficacious dual regimen of trimethoprim-sulfamethoxazole (TMP-SMX). Extending the previous work of Dutz (1970) and Frenkel (Frenkel et al. 1966), Hughes et al. showed that this combination was highly effective for both prophylaxis and therapy of the infection (Hughes et al. 1974a).

During the 1960s and 1970s, the major target populations for *Pneumocystis* pneumonia were children with primary immunodeficiency diseases and patients of all ages receiving corticosteroids and other immunosuppressive therapy to prevent rejection of organ transplants and for the treatment of cancer. Most patients were responsive to TMP-SMX and its widespread use was associated with a dramatic decline in the number of cases of *Pneumocystis* pneumonia at most major medical centers in the USA.

Pneumocystis pneumonia (PCP) once again became a focus of medical attention during the 1980s as the most common opportunistic infection of individuals with the acquired immunodeficiency syndrome (AIDS) (Mills 1986). Unlike the previous subpopulations infected with *Pneumocystis*, AIDS patients experienced a more subtle clinical presentation, slow response to treatment, recurrent infections, and a high rate of adverse reactions to TMP-SMX.

During the early years of the AIDS epidemic, only a rudimentary knowledge of the organism's basic biology, structural and antigenic characteristics, and molecular genetics existed. Despite a lack of continuous in vitro propagation system and undefined life cycle, almost three decades of concerted basic and applied research has resulted in a better understanding of the family of organisms once known singularly as *Pneumocystis carinii*. Sequence analysis of the 16S-like ribosomal RNA gene as well as protein-encoding genes revealed members of the *Pneumocystis* genus to be fungi rather than protozoons as once thought. In response, pharmaceutical companies began development of novel anti-*Pneumocystis* compounds targeted to unique fungal processes, such as cell wall synthesis (Schmatz et al. 1990, 1995). Molecular and antigenic studies support species distinctions for organisms residing in different mammalian hosts, and in some cases, for different species of *Pneumocystis* within the same mammalian host. The process of naming and describing individual species has begun.

Although the incidence has declined significantly from 1992 through 1997 for each of 15 of the 26 specific AIDS-defining opportunistic infections (OI) including PCP ($P<0.05$), PCP remains as the most common AIDS-defining OI to occur first, in 36 percent of individuals infected with the human immunodeficiency virus (HIV) (Jones et al. 1999). PCP was the most common AIDS-defining OI (274 cases per 1 000 person-years), and the most common AIDS-defining OI to have occurred during the course of AIDS (53 percent of persons who died with AIDS had PCP diagnosed at some time during their course of AIDS).

The administration of highly active anti-retroviral therapy (HAART) targeting the HIV infection reduced dramatically the incidence and mortality of *P. jirovecii*. However, a growing body of evidence indicates that *P. jirovecii* populations are evolving resistance to current therapies, with specific mutations in the target genes of sulfamethoxazole (dihydropteroate synthase) (Beard et al. 2000; Huang et al. 2000; Navin et al. 2001) and atovaquone (cytochrome bc_1) (Walker et al. 1998; Armstrong et al. 2000; Kazanjian et al. 2000, 2001, 2004). Eradication of *Pneumocystis* with the currently available therapies is unlikely. Concomitant with the lack of knowledge of the infection's transmission and life cycle, history predicts a re-emergence of PCP. In this chapter, the current state of knowledge in many areas of *Pneumocystis* investigation will be reviewed. Care was taken to include key historical studies as well as the most recent reports on each subject.

THE ORGANISM

Pneumocystis are eukaryotic fungal organisms found in low number in the lungs of mammalian hosts with intact immune systems and in more abundance in homeotherms with compromised immune status. Most mammalian species have been reported to harbor organisms with morphology ascribed to *Pneumocystis*, although marine mammals and some exotic species have not been adequately evaluated. *Pneumocystis* has not been detected in surveys of poikilotherms or birds, although antibodies were detected in one study measuring the serological responses of chickens to rat-derived *Pneumocystis* (Settnes et al. 1994).

Morphology and life cycle

The nomenclature associated with descriptions of the life cycle stages and morphological features of *Pneumocystis* bears many remnants of its previous classification as a protozoan parasite. In this chapter, terms more suitable for a fungus are introduced (Cushion et al. 1997b; Ruffolo 1994). Because *Pneumocystis* has been refractory to all attempts to propagate it in vitro, histochemical and ultrastructural analyses of organisms found in human and

rat lungs have significantly contributed to the current understanding of its life cycle and morphology.

MORPHOLOGY

The morphology of *Pneumocystis* found in the lungs of various mammalian hosts is quite similar, with only subtle ultrastructural differences reported between rabbit-, mouse-, and rat-derived organisms (Dei-Cas et al. 1994; Nielsen et al. 1998). Most investigators have relied on the immunosuppressed rat model of PCP for morphological analyses because of the ease of obtaining tissue for study.

Three developmental forms of *Pneumocystis* are generally recognized: the trophic stage, precyst, and cyst. A filamentous phase has not been identified and attempts to detect an environmental cycle in which amplification takes place have been unsuccessful. Proposed life cycles have relied exclusively on microscopic observations of developmental forms found in infected mammalian lungs.

The trophic form

The trophic form of *Pneumocystis* is the smallest of its life cycle stages. These forms range in size from 1.5 to 5.0 μm and are ellipsoid in shape when viewed by light microscopy of unfixed preparations, but can appear ameboid in appearance after fixation and analysis by electron microscopy (Ruffolo 1994) (Figure 1a). Trophic forms are thought to reproduce by binary fission, with some evidence of this process provided by electron microscopy (Campbell 1972; Richardson et al. 1989; Yoshida 1989). This stage of the organism has been subdivided by some investigators into 'small' and 'large' categories, the primary characteristics of each category being:

- overall size
- the presence or absence of tubular extensions on the cell surface
- size of nucleus
- number of glycogen granules and cellular inclusions.

Since the smaller trophic form is presumed to be the direct product of excystation (spore release), it is reduced in size (1.5–2.0 μm) and contains fewer inclusions. The larger trophic form is thought to represent the vegetative stage and thus has more cellular inclusions and a larger nucleus as it proceeds towards mitotic division. Cytoplasmic organelles include a nucleus (~0.5–1.0 μm) bounded by a typical nuclear envelope with pores, which at times is associated with a nucleolus; usually a single mitochondrion with lamellar cristae which can be branched or irregular in shape (Palluault et al. 1991; Ruffolo et al. 1989); rough endoplasmic reticulum usually contiguous with the nucleus; ribosomes; occasional vacuoles; and glycogen granules. Smooth endoplasmic reticulum and Golgi-like vesicles were described in *Pneumocystis* from neonatal rabbits (Palluault et al. 1990).

Freeze fracture and transmission electron microscopy have revealed that the trophic forms are circumscribed by two distinct unit membranes separated by a thin electron-lucent space (Campbell 1972; De Stefano et al. 1990b). A dense matrix associated with the outermost membrane contains polysaccharides, the predominant surface antigen of the organism [the major surface glycoproteins (MSG)] and several classes of host-derived molecules, e.g. cardiolipin, fibronectin. The entire complex spans 20–50 nm. The lack of staining with methenamine silver (used for diagnosis of fungal infections and PCP) by this form of the organism is probably due to the almost nonexistent electron-lucent layer thought to be composed in part of β-glucan (De Stefano et al. 1990a). Usually present only on the surface of large trophic forms is a feature called 'tubular expansions or extensions' (Yoshida 1989; Dei-Cas et al. 1991). Ultrastructural studies show them as long, thin, coiled, membranous structures filled with electron-dense granular material, the function of which is not known but suggested to be a means of adherence to host cells or for uptake of nutrients (Figure 1c, d).

The observation that some trophic forms are ameboid in appearance has led some investigators to assume that at least this stage is motile (Campbell 1972; Haselton et al. 1981). By contrast, studies with live organisms have not supported this contention (Shiota 1984; Cushion et al. 1988), and the presence of cytoskeletal elements indicative of motility (e.g. microtubules, microfilaments supporting the membrane) has not been detected in trophic forms.

The precyst

The precyst (sporocyte) is recognized as an intermediate stage of the sexual phase of reproduction leading to cyst development. It is presumed that a mating event first occurs to provide a zygote which initiates sporogenesis. The zygotic nucleus undergoes meiosis and a subsequent mitosis within the sporocyte. Sporocyte development has been characterized as early, intermediate, and late. An early sporocyte has an oval shape, a cell wall of 40–50 nm containing the two unit membranes with a widening electron-lucent space, and contains several mitochondria which may be clumped around the diploid nucleus (Figure 2a, b). Ultrastructural studies of this early stage have revealed the only morphological evidence for sexual reproduction of *Pneumocystis*, the presence of synaptonemal complexes, indicating a meiotic prophase (Matsumoto and Yoshida 1984). During the intermediate sporocyte stage, the zygotic nucleus meiotically divides to yield four nuclei, while the cell becomes more spherical and the electron-lucent space between the two membranes continues to enlarge. Cytoplasmic inclusions characteristic of this stage include spindle microtubules, which appear to arise from a dense body called the nucleus-associated organelle (NAO) (Matsumoto and Yoshida 1984). The

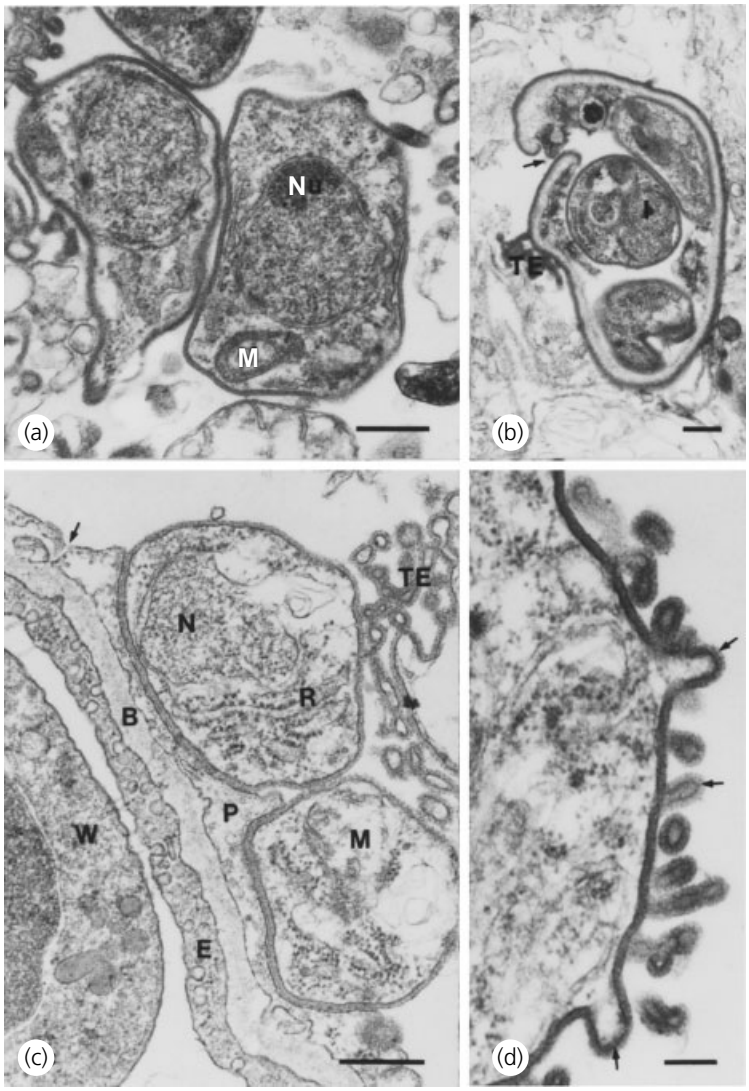

Figure 1 *Trophic forms of* P. carinii. **(a)** *The small trophic forms lack tubular extensions. A prominent nucleolus (Nu) is adjacent to the nuclear envelope of the trophic form on the right. A mitochondrion (M) and endoplasmic reticulum (R) can be observed in the same trophic form.* **(b)** *Mature intracystic bodies (ICB) (spores) are thought to be released through ruptured cyst (spore case) walls (arrow). A mature ICB (I) has the same structure as the small trophic form. Tubular extensions (TE) are also present.* **(c)** *Small trophic forms adhere tightly to the type I pneumocyte (P). The alveolar endothelium is discontinuous (arrow). Tubular extensions (TE) are evident on the alveolar lumenal side of the trophic forms. The type I pneumocyte lies adjacent to the basement membrane (B) which separates the endothelial cells (E) that line the capillary. A white blood cell (W) appears in the capillary lumen. A nucleus (N) is also present.* **(d)** *The surface of the trophic form consists of two unit membranes and a thick external glycocalyx. Tubular extensions show continuity with the cell surface (arrows). The bar lines represent 0.5 μm in Figures 1, 2 and 3, except in Figure 1* **(d)** *and Figure 2* **(b)**, *where it represents 0.2 μm. Figures 1, 2 and 3 are modifications of those appearing in Schrager et al. (1993).*

late sporocyte is defined by its spherical shape and prominent three-layer cell wall (80–120 nm). This form contains a total of eight nuclei resulting from mitotic division of the products of meiosis, aggregated mitochondria, and the presence of unit membranes within the cytoplasm, apparently for compartmentalization of the organelles into spores and completion of sporogenesis.

The cyst stage

The cyst stage (spore case, ascus) is the end product of sporogenesis. This form is spherical, 5–8.0 μm in diameter, and has a thick cell wall composed of the three layers (Figure 2c). Eight spores are commonly found within the case. *Pneumocystis* asci are of the protunicate type, characterized by a thin delicate wall and passive discharge of their ascospores. The other two types of asci found in the ascomycetes, unitunicate and bitunicate, actively discharge their spores by forcible ejection (Liu and Hall 2004). Biochemical analyses and staining reactions provide strong evidence for the presence of substantial amounts of glucan in the spore case cell wall and there is some evidence that chitin or at least, *N*-acetylglucosamine may also be

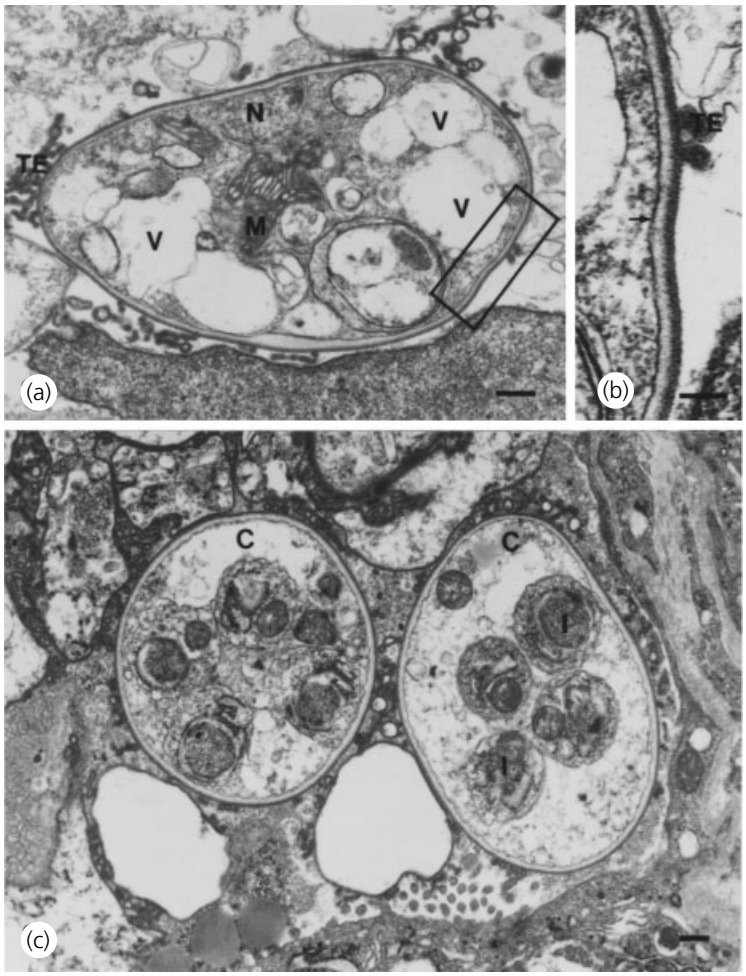

Figure 2 *Precyst and cysts (sporocytes and spore cases).* **(a)** *Aggregation of mitochondria (M) are a characteristic of precysts (sporocytes). Lamellar cristae can be seen in these organelles. Vacuoles (V), tubular extensions (TE), and a nucleus (N) are also present.* **(b)** *Higher magnification of the sporocyte surface within the rectangle in* **(a)** *shows the plasma membrane (arrow) and a thickened cell wall consisting of an inner electron-lucent region and an outer electron-dense layer in which the second unit membrane is enmeshed. Tubular extensions are reduced in number in precysts (sporocytes) and cysts (spore cases–I.C).* **(c)** *It is presumed that as the spore cases mature, nuclei and cytoplasm are segmented into ICB/spores (I) within the spore cases.*

present (Garner et al. 1991; De Stefano et al. 1992). The spores are spherical, 1–2 μm in diameter, contain the same organelles of the small trophic forms, and are bounded by two unit membranes. One irregularity of the spore case cell wall can be observed at one of the poles, where a thickening of the electron-lucent space is apparent by electron microscopy and by light microscopy of methenamine silver stained organisms or interference contrast microscopy of unstained organisms (Ruffolo et al. 1986). Membranous particles, mitochondria, and unincorporated cytoplasm are often present at this location.

The process of spore release is not well documented, except by Shiota (1984) who described the excystation of spherical and elongated intracystic bodies using light microscopic techniques. Prior to release, the spores have been reported to exhibit a variety of shapes, such as:

- spherical, which imparts a rosette array within the spore case
- large and irregular shapes that seem to be tightly packed into the case
- elongated banana-shaped spores that often exhibit dense cytoplasm
- ellipsoidal forms that sometimes appear as if attached to stalks.

Contractile-like movement was observed in some light microscopic studies of the ellipsoidal and elongated shaped spores (Shiota 1984; Cushion et al. 1988) and subsequently documented by videomicroscopy (Newsome et al. 1991). Neither the function of the various shapes nor the significance of the movement is understood. Empty spore cases are frequently observed by light and electron microscopy and assume a crescent shape. In some, a rent in the wall is evident (Figure 3). Within

Figure 3 *Collapsed cyst (spore case). A cresent-shaped collapsed spore case (C). A trophic form (T) is also shown. The spores have been released, presumably through a rent in the cell wall (arrow). The residual cytoplasm has begun to degenerate.*

the collapsed thick wall, a remaining spore may be observed as well as residual cytoplasm.

In addition to the archetypal thick-walled form, a thin-walled cyst has been described by some investigators (Vossen et al. 1978; Matsumoto and Yoshida 1986). This stage contains large irregularly shaped 'daughter forms' that fill the entire cell which is delimited by a cell wall lacking the inner electron-lucent layer.

LIFE CYCLE

The intrapulmonary life cycle of *Pneumocystis* likely involves an asexual phase of cell division by the apparent haploid trophic form and sexual phase (sporogenesis) leading to the production of a thick-walled reproductive cyst (spore case, ascus) containing eight intracystic bodies (spores) (Figure 4). An additional asexual cycle leading to formation of a thin-walled cyst (endogeny) has been proposed (Vossen et al. 1978; Matsumoto and Yoshida 1986).

Several life cycles of *Pneumocystis* have been described. All relied upon organism morphologies observed in infected lungs by techniques of light and electron microscopy and not by direct observations made from replicating organisms (Walzer et al. 1989). Thus, the complete life cycle of *Pneumocystis* is not known, but has been deduced from static images and based on the life cycles of other protists, especially parasitic protozoa, but more recently, fungi (Cushion 2004b). It is hoped that a clearer understanding of the fungal nature of *Pneumocystis*, coincident with improvement in ex vivo culture conditions, will lead to definition of its life cycle.

The asexual replication of the trophic forms appears to resemble binary fission, rather than budding, a process used by many but not all yeasts. *Schizosaccharomyces pombe* is one yeast that divides by binary fission and also has a sexual phase initiated by morphologically indistinguishable mating types. *S. pombe* is phylogenetically related to *Pneumocystis* (see below) and it is conceivable that they share some similarities between their life cycles.

In 1984, Matsumoto and Yoshida provided ultrastructural evidence for sexual reproduction (Matsumoto and Yoshida 1984). Synaptonemal complexes, zipper-like conformations which occur during pairing of homologous chromosomes, were observed in a *Pneumocystis* life cycle stage the authors called an 'early precyst.' If sexual reproduction does take place, cyst development would necessarily follow a mating event. Ultrastructural observation of binucleate trophic forms has been interpreted as resulting from conjugation (Yoshida 1989), but could just as easily represent binary fission. The trophic forms/trophozoites involved in this process have been postulated to be 'isogametes' because of the lack of morphological characteristics to distinguish male or female forms. However, isogametes are usually associated with a protozoan life cycle. Rather, the trophic forms may be more akin to the mating types of yeast which are, in general, morphologically indistinct, but are defined by pheromones and receptors encoded by mating type-specific genes (Herskowitz 1989). For example, in the ascomycete family, *Saccharomyces cerevisiae* has two mating types, 'α' and '**a**,' and *S. pombe* has 'minus (−)' and 'plus (+).' Since the mating process in yeast is usually initiated by an environmental stress, e.g. nitrogen starvation, perhaps sporogenesis of *Pneumocystis* is induced by unfavorable conditions in the mammalian lung brought about by an increasing organism burden or depletion of nutrients.

Molecular genetic techniques have led to significant advances in our understanding of the *Pneumocystis* life cycle. Like that in yeast, the sexual cycle likely involves coordination of mating types. The process is initiated by attachment of the pheromone from one mating type to the other's receptor. In yeast, the receptor *STE2* in **a** cells is recognized by **α**-factor and the receptor *STE3* of α cells is recognized by **a**-factor. The complementary binding results in signaling to the interior of the cells via a heterotrimeric G protein complex, then to a mitogen-activated kinase cascade. Activation of Ste12p stimulates the cells into expression of mating type genes, cell cycle arrest, fusion of mating types, and nuclear fusion (Herskowitz 1989). Within the genome of *P. carinii* lies homologs to *STE3*, *STE2*, *STE11*, *STE12*, *STE20*, and Gpa1(Smulian et al. 1996, 2001), suggesting that the organisms do indeed mate and can transduce this signal via the appropriate signal cascade. The *P. carinii* Ste12 homolog (which also has homology to the Ste11 of *S. pombe*) was shown to be phosphorylated by a map kinase of *P. carinii* (PCM) (Vohra et al. 2003b). A homolog of the **a** mating

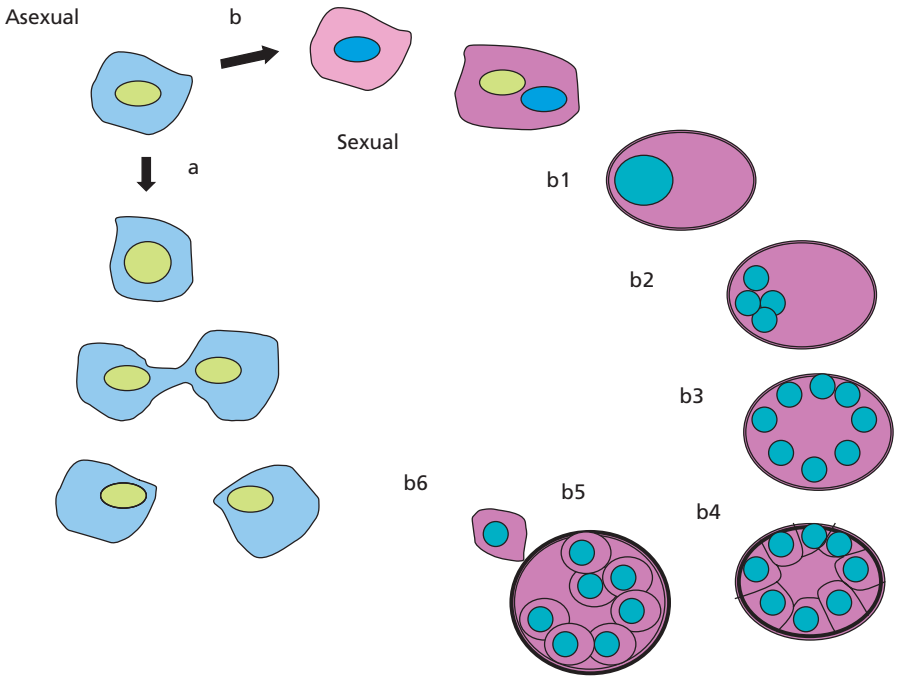

Figure 4 *Proposed life cycle of* P. carinii. *Trophic forms of opposite mating type (shown as blue or pink) can undergo asexual binary fission* **(a)** *or enter into sexual reproduction via mating* **(b)**. *Asexual phase* **(a)**. *Trophic forms replicate by mitosis where the haploid nucleus replicates, cytoplasmic volume increases, and the cell splits by simple cell division. No budding has been observed in the life cycle of* Pneumocystis. *Sexual phase. Haploid trophic forms (mating types, blue and pink) conjugate to form a diploid zygote (early phase sporocyte) (b1) which undergoes meiosis (b2) and subsequent mitosis (b3) to form eight haploid nuclei (late phase sporocyte). The spores are formed by compartmentalization of nuclei and cytoplasmic organelles, e.g. mitochondria (b4). Release is thought to occur through a rent in the cell wall (b5). The ascospores then emerge and become the vegetative stage, or trophic forms, which presumably can enter either phase of division (b6).*

factor was found flanking the *STE3* gene of *P. carinii* (Smulian et al. 2001). The linkage of an **a**-factor pheromone with an **a**-factor receptor has not been reported for any other member of the fungi. Despite the lack of in vitro system and thus, any molecular tools to evaluate function, investigators in the field have relied upon expression in heterologous systems like yeast and *S. pombe*, with generally good rates of success (Thomas et al. 1998; Fox and Smulian 1999; Vohra et al. 2003a). This approach will be invaluable for definition of the complete replication cycle and other pathways of *P. carinii*.

Putative gene homologs that function in mitotic and meiotic replication in other fungal systems have been identified through the *Pneumocystis* Genome Project (Porollo et al. 2004) and by investigators in the field (Thomas et al. 1996, 2001; Gustafson et al. 1999; Vohra et al. 2003b). A partial summary of the homologous genes involved in cell division and replication from the Expressed Sequence Tag (EST) portion of the Genome Project has been reported (Cushion 2004b).

HOST RANGE

Early surveys of wild and domestic animal populations used microscopic methods for detection of *Pneumocystis*. Presence of organisms consistent with the morphology of the cyst form of *Pneumocystis* in the lungs of mammals was used as the diagnostic criteria. Later studies have relied upon the polymerase chain reaction (PCR) with primers targeting the mitochondrial large subunit (mtLSU) of the ribosomal RNA in most cases. Both standard and nested PCR techniques have been used. Table 1 summarizes the majority of these reports. The organisms were detected in phylogenetically disparate classes of mammals spanning rodents, canines, felines, ungulates, and primates. A recent study using nested PCR surveyed a large number of diverse species of nonhuman primates and found evidence supporting the coevolution of the *Pneumocystis* species with their distinct host (Hugot et al. 2003). A striking finding of this study was the genetic diversity of *Pneumocystis* populations as well as their prevalence within the primates (20–100 percent). *Pneumocystis* was also detected with high frequency in wild shrews, ranging from 30–70 percent of the animals sampled (Laakkonen and Henttonen 1995; Laakkonen and Soveri 1995; Bishop et al. 1997). The presence of *Pneumocystis* has not been reported in any of the poikilotherms, although a detailed survey of such animals is absent from the literature. Studies of members of the Aves kingdom have not found evidence of *Pneumocystis* using both microscopic and molecular genetic methods, although some antibodies to rat-derived *Pneumocystis*

Palm squirrel			
Red panda			
Fennec fox			
Tree hyrax			
Large-toothed hyrax			

were detected in the sera from some birds (Settnes et al. 1994). Temperature may play a role in the organism's proclivity for mammals, as birds maintain a higher basal temperature than mammals, at approximately 41°C, and poikilotherms have variable temperatures only slightly higher than the ambient temperature. As discussed later in this chapter, the organism populations harbored by the different species of mammals are genetically and phenotypically distinct, warranting the formal process of naming of these *Pneumocystis* species.

TAXONOMY AND PHYLOGENY

Since the publication of the previous, 9th edition of this text in 1998, there has been a general acceptance within the scientific community that members of the genus *Pneumocystis* are bonafide fungi, albeit 'atypical' fungi. Individual gene sequence comparisons and the fungal homologies of a large number of putative genes produced by the *Pneumocystis* Genome Project have contributed in large part to this consensus. With the question of 'What are they, exactly?' (Stringer 1996) apparently settled, the issue of describing distinct species within the genus has become the focus of attention. In this section, a summary of the controversy regarding the fungal versus protozoan nature of *Pneumocystis* will be presented. The newly named species within the genus will be highlighted as well as the studies and observations that lead to these distinctions.

Beginning with its first identification as a life cycle stage of a trypanosome by Carlos Chagas in 1909, the taxonomy and phylogenetic classification of *Pneumocystis* has been fraught with controversy. The Delanöes believed it to be a protozoan and that assertion was generally accepted by the rather uninterested scientific community. After *P. carinii* was found to be the etiologic agent of epidemic interstitial plasmacellular pneumonia in the 1950s, a renewed effort to classify it was initiated. Application of the tools available at that time, including vitro culture, microscopic analysis, histological staining, and animal inoculation experiments, resulted in two divided opinions; that *P. carinii* was a protozoan or that it was a fungus (Gajdusek 1957).

Ultrastructural studies of the 1960s and 1970s reached 'conclusions' similar to those of the earlier microscopists, that *Pneumocystis* was a protozoon or a yeast, based on the 'characteristic' cellular structures of the cyst and trophic forms. Exploiting the immunosuppressed rat model of pneumocystosis established by Frenkel in 1966, investigators were able to compare organisms obtained from rats with those from humans. In 1967, Barton and Campbell concluded that the organisms identified as *Pneumocystis* in rat lungs most likely were protozoons based on the presence of a protozoan-like pellicle and predicted motility as indicated by morphological features identified as 'pseudopodia' in the trophozoites (Barton and Campbell 1967, 1969). In 1972, Campbell confirmed the structural similarities of rat and human-derived *Pneumocystis* and again underscored the protozoan nature of the organism, adding the presence of filopodia as an additional feature supporting this contention (Campbell 1972). In contrast, Vavra and Kucera in 1970 reached the conclusion that *Pneumocystis* was a yeast after extensive ultrastructural analyses of rat and human organisms (Vavra and Kucera 1970). They found the morphology of the intracystic bodies within the cyst similar to ascospores within the ascus of yeasts like *Saccharomyces*. In addition, the organization of the cell membrane and wall were likened to those observed in *Rhodotorula* or *Coccidioides immitis*, and the lamellar cristae of the mitochondria reminiscent of the yeast organelle. Placement in the Ascomycetes was

tentatively proposed with verification once a culture system was found.

More recent ultrastructural studies echo the same conundrum. In 1984, Matsumoto and Yoshida not only provided evidence for meiosis as a means of reproduction for *Pneumocystis* (the presence of synaptonemal complexes) but proposed a life cycle with striking similarity to that of a protozoan parasite with isogamous gametes (Matsumoto and Yoshida 1984). Studies by Ruffolo and colleagues (Ruffolo et al. 1989) reported the morphology of the cristae in *Pneumocystis* mitochondria to be lamellar, rather than vesicular, and the process of daughter cell formation more like that of a fungus. There are no morphological features of *Pneumocystis* entirely consistent with either a yeast or protozoan classification. Ultrastructural analysis of the cyst wall by De Stefano et al. (1990b) confirmed an earlier finding of Bommer (1962) which described two unit membranes, a plasma membrane delimiting the daughter forms as well as an outer membrane enmeshed within the dense carbohydrate matrix of the cyst wall. A two-membrane outer layer is more reminiscent of protozoons than any common fungus. Most investigators recognized the limitations of ultrastructural analyses for taxonomic purposes, especially in the case of *Pneumocystis* which cannot be cultured in vitro to provide further verification of their observations.

Compositional analyses of the lipids and carbohydrates of *Pneumocystis* have not yet yielded any signature molecules that would define its taxonomic placement. Rather, these studies confirmed the atypical nature of this family of organisms. Instead of finding ergosterol as the main structural sterol, as is the case with most yeast, cholesterol was the bulk sterol in *P. carinii* (Kaneshiro et al. 1989). Kaneshiro et al. have suggested that cholesterol (C27), is probably totally scavenged from the host. By contrast, another study provided evidence that cholesterol could be synthesized, at least in part, by the organism (Zhou et al. 2002). Gas chromatography-mass spectrometry (GC-MS) analyses of the monosaccharide fragments of the carbohydrates of the cyst wall and cytoplasmic contents of *P. carinii* identified glucose as the major constituent; mannose and galactose were present in equal ratios; *N*-acetyl-D-glucosamine was found in lesser amounts, while trace amounts of ribose and sialic acid were present. Sugars were representative of about 8 percent of the cyst wall components, a somewhat lower amount than most fungi (De Stefano et al. 1990a). In contrast to the rat-derived carbohydrate analyses, high-pressure liquid chromatography (HPLC) analyses conducted by Lundgren et al. found mannose, glucose, galactose, and glucosamine to be present in *P. jirovecii* at equimolar concentrations (Lundgren et al. 1991). The presence of chitin was inferred by lectin binding (Garner et al. 1991), but enzymes involved in chitin biosynthesis have not yet been detected in its genome.

Molecular biological analyses

There is overwhelming genetic evidence supporting the fungal identity of *Pneumocystis*. Whereas consideration of morphological characteristics, biochemical composition, or drug susceptibilities produced no definitive phylogenetic association, the use of molecular genetic tools initiated in 1988 provides a distinct answer to the question of the phylogenetic placement of this complex of organisms. *Pneumocystis* have been placed in the Phylum Ascomycota; the Subphylum Taphrinomycotina (syn. Archiascomycotina); Class Pneumocystidomycetes; Order Pneumocystidales; and Family *Pneumocystidaceae* (Eriksson and Winka 1998). The Taphrinomycotina are a paraphyletic assemblage of basal taxa and the identity of the closest extant relative of *Pneumocystis* remains unsettled, with phylogenetic results varying by gene sequence used and method for construction. The morphologies and biochemical characteristics of the fungi within this group are highly diverse and include such members as the fission yeast *S. pombe*, the plant pathogen *Taphrina deformans*, and *Neolecta vitellina*, the only member with a fruiting body structure (Liu and Hall 2004).

SMALL SUBUNIT RRNA SEQUENCES

Sequence comparison of rRNA genes is the most widely used method for studying phylogenetic relationships among prokaryotic and eukaryotic microbes (Vandamme et al. 1996). Both the large and small nuclear ribosomal RNA genes contain regions that are conserved and evolve at a slower pace as well as other regions that are more rapidly evolving and have increased sequence variation. Comparisons of sequences at the more conserved regions are used to predict more inclusive relationships such as kingdom, while the variable regions are used to define the closer associations, e.g. genus, species. Two laboratories reported the fungal nature of *P. carinii* based on comparisons of the DNA gene sequence of the small subunit ribosomal RNA (16S) gene (Edman et al. 1988) and of cDNA from the same gene of *P. carinii* (Stringer et al. 1989). Construction of several phylogenetic trees based on 16S-like sequence infer a relationship of *P. carinii* with the ascomycetes *S. cerevisiae*, *S. pombe* or *T. deformans* (Gargas et al. 1995) (Figure 5).

5S RNA SEQUENCE

Sequencing of the 5S RNA gene showed a relationship with the 'Rhizopoda/Myxomycota/Zygomycota group' (Watanabe et al. 1989). The 16S-like genes have replaced the 5S genes for phylogenetic analyses because of associated evolutionary clock anomalies and ambiguities due to the short 120 bp sequence length.

MITOCHONDRIAL GENE SEQUENCES

The use of the mitochondrial genome as an evolutionary clock has been questioned because of their supposed

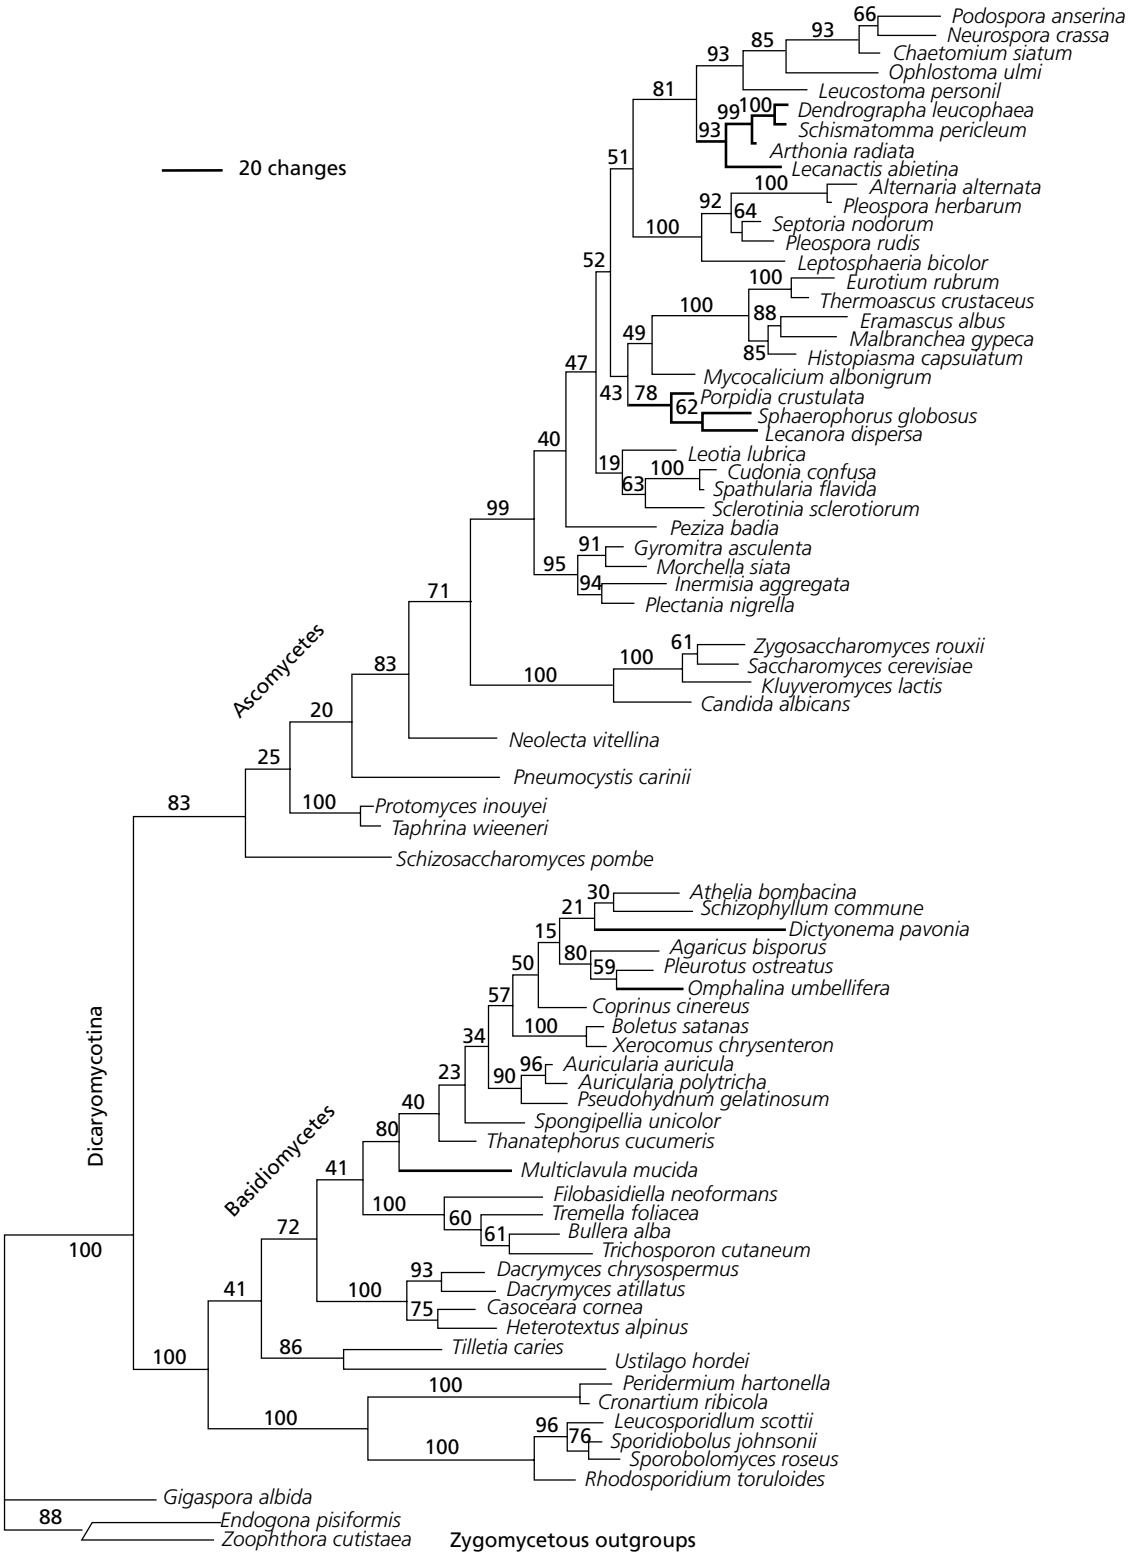

Figure 5 *Phylogeny of* Pneumocystis carinii. *Reprinted from Gargas et al. 1995*

bacterial origins and endosymbiotic lifestyles that probably arose more than once throughout microbial evolution. Nonetheless, comparison of several *Pneumocystis* mitochondrial genes supports the fungal identity of the organism. Comparison of the putative amino acid sequences of the entire genes or portions of the mitochondrial cytochrome oxidase II, apocytochrome *b*, *NADH 1*, *NADH 2*, *NADH 3*, *NADH 6* genes from

P. carinii with like genes from three fungi and two protozoans showed greater homology to the fungi than to the protozoans (Pixley et al. 1991). Comparison of the mitochondrial small subunit rRNA secondary structures of representative members of the fungi and protozoa with *Pneumocystis* sequence supported its fungal identity. Wakefield et al. (1992) employed a strategy whereby oligonucleotide primers were targeted to a sequence specific for a portion of the large subunit of the mitochondrial RNA of *P. carinii*. A series of fungi representing genera of Ascomycota and Basidiomycota were subjected to the PCR under conditions of reduced stringency. Members of the ustomycetous red yeast fungi were found to produce amplicons with these primers. Comparisons of gene sequences from these basidiomycetes with those of *P. carinii* inferred a relationship among these organisms. However, placement of *Pneumocystis* among the basidiomycetes has not been upheld by recent data from the *Pneumocystis* Genome Project (pgp.cchmc.org) or by comparisons of other genes (Liu and Hall 2004). Rather, BLAST analyses (Altschul et al. 1990) of cDNA and genomic sequences of *P. carinii* show that the greatest majority of putative genes have homology to the ascomycetes, *S. pombe*, *S. cerevisiae* and *Neurospora crassa* (Cushion et al. 2004b).

ELONGATION FACTOR 3

Identification of the *Pneumocystis* gene for translation elongation factor 3 (EF3) provided strong evidence for a fungal ancestry (Ypma-Wong et al. 1992). This factor is essential for protein synthesis in fungi but not in other eukaryotes. Alignment of the deduced amino acid sequence showed 57 percent identity with *S. cerevisiae* and *Candida albicans* EF3 proteins, while comparison of the *S. cerevisiae* and *C. albicans* amino acid sequences showed a 78 percent identity. These data suggest that *Pneumocystis*, although a member of the fungi, is significantly divergent from other fungi.

RNA POLYMERASE II

Slowly evolving genes that encode proteins are being routinely used to infer phylogeny. These genes are usually those in replication, transcription, and translation of genetic material and did not arise from horizontal transfer (Sicheritz-Ponten and Andersson 2001). One such gene is that encoding the second subunit of the nuclear DNA-dependent RNA polymerase II (*RPB2*). This and other protein-encoding genes have been found to resolve internal branches that were unresolved in rDNA trees (Liu and Hall 2004). Analyses of the *RPB2* gene from *P. carinii*, and those from 60 other fungi including seven basiodiomycetes as outgroups, supported the small subunit rRNA trees in its placement in the Taphrinomycotina, but differed in its closest fungal affinities. Maximum parsimony with bootstrap values greater than 40 percent showed a closer affinity with *S. pombe*, while Bayesian inference with a posterior probability of 97 percent placed *P. carinii* with the plant pathogen *T. deformans* (Liu and Hall 2004).

COMPARISONS OF OTHER GENE SEQUENCES

Several other protein-encoding genes from *Pneumocystis* have been sequenced and compared with like genes from protozoans and fungi. Edlind et al. found the β-tubulin gene to be more homologous with the genes of filamentous fungi (89–91 percent) such as *N. crassa* than with those of yeasts such as *S. pombe* (Edlind et al. 1992). The thymidylate synthase (*TS*) and dihydrofolate reductase (*DHFR*) genes in protozoa are fused and encode a bifunctional protein (Garret and Coderre 1984). In the yeasts and mammals evaluated thus far, these genes are separate. In 1989, it was shown that *Pneumocystis* encodes these proteins with separate genes found on separate chromosomes (Edman et al. 1989a, b). Construction of phylogenetic trees with limited numbers of fungal and protozoal members using *TS* and *DHFR* sequences supported the association of *Pneumocystis* genes with ascomycetes and basidiomycetes. Similar studies with transcription factor IID and a P-type cation-translocating ATPase gene (Stringer 1993) also supported the fungal identity of *Pneumocystis*.

GENETIC DIVERSITY OF *PNEUMOCYSTIS* FOUND IN DIFFERENT MAMMALIAN HOSTS

It has long been appreciated that there are differences among the antigenic reactivities of *Pneumocystis* obtained from the lungs of different mammalian hosts (Graves et al. 1994). Molecular genetic evidence supports these initial findings. Comparison of the srRNA and mitochondrial large ribosomal subunit RNA, and *TS* gene sequences between rat, human, mouse, ferret, and pig *Pneumocystis* shows differences similar to those observed between different yeast species (Keely et al. 2004). Likewise, the sequences of genes from the multigene family encoding the MSG of *Pneumocystis* are quite distinct, supporting the observed antigenic reactivities of the expressed proteins (Gigliotti et al. 1993a; Kovacs et al. 1993; Stringer et al. 1993; Wada et al. 1993; Keely et al. 1994; Sunkin et al. 1994). Comparison of the sequence of a portion of the 5-enolpyruvyl shikimate phosphate synthase, a gene in the *arom* locus, among rat-, human-, mouse-, rabbit-, and ferret-derived *Pneumocystis* showed divergence at the nucleotide level ranging from 7 to 22 percent and at the deduced amino acid sequence level of 7–26 percent (Banerji et al. 1995). The human and rat *Pneumocystis* α-tubulin gene were 92 percent identical in their predicted amino acid sequence and 26 percent divergent in the nucleotide sequence (Stringer 1993). Table 2 illustrates some of these differences.

Table 2 *Pairwise distances (percent) of six* Pneumocystis *genes*

a) *P. jirovecii* was compared to non-human primate-derived *Pneumocystis* from owl-monkey and macaque.

Electrophoretic karyotypes from rat, mouse, human, and ferret *Pneumocystis* have been shown to be distinct (Stringer and Cushion 1998; Weinberg and Bartlett 1991) (see Figure 6). The rat *Pneumocystis* profiles from *P. carinii* and *P. wakefieldiae* ranged between 700 and 300 kb with 13–15 bands, with estimated total genome sizes of 8.2 and 7.7 Mb, respectively. *P. murina* from mouse contained 15–16 bands within a shorter range of 600–350 kb but with a similar estimated genome size of 8.2 Mb. The human *P. jirovecii* karyotype of 12 bands ranged in size from 800 to 350 kb with a unique band at approximately 800 kb and an estimated genome size of 7.0 Mb. *Pneumocystis* from ferret produced the most distinct karyotype, with about 13 bands separating between 525 and 700 kb and one large band at ~850 kb with the largest estimated genome size for *Pneumocystis* species to date, 11.0 Mb.

Supporting the concept of species specificity were the negative results from several animal studies in which *Pneumocystis* obtained from one host was inoculated or injected into different immunosuppressed recipient hosts. For example, Gigliotti et al. attempted to inoculate severe combined immunodeficiency disease (SCID) mice with *Pneumocystis* derived from immunosuppressed ferrets and tracked the infection with *Pneumocystis*-specific molecular markers (Gigliotti et al. 1993b). No cross-infection could be detected.

GENETIC DIVERSITY WITHIN A SINGLE HOST

Rat

The presence of two genetically distinct *Pneumocystis* residing in the same infected rat lung was described in 1992 by detection of divergent 5.8S and 26S rRNA sequences (Liu et al. 1992). That these two 'sequovars' were from two discrete genomes was reported in 1993 using a combination of pulsed-field gel electrophoresis (PFGE), Southern hybridizations, and gene sequence comparisons (Cushion et al. 1993). The karyotpe profiles of the two populations, termed 'prototype' and 'variant' at that time, produced by PFGE were distinct (Figure 6) and hybridization with eight single-copy gene probes to the Southern blotted profiles resulted in localization to chromosomes of different sizes (Cushion et al. 2004a). Of note, 13 patterns of karyotypic profiles have been identified from rats infected with the 'prototype' population (Rebholz and Cushion 2001) while only a single profile has emerged for the 'variant' organism. The most common profile of 'prototype,' form 1, is illustrated in Figure 6. The form 1 genome was chosen as the first *Pneumocystis* to be sequenced (Cushion and Arnold 1997). Both populations were often found within the same rat colony (identified by PFGE profiles), and many of the infections (within the same rat lung) were composed of both organisms (Cushion et al. 1993).

The small subunit rRNA sequences of these two *Pneumocystis* populations were 6.6 percent divergent in a highly variable region of the gene. The sequence differences in each population have been reported at several other loci and ranged from 4 to 31 percent (Table 3). Such levels of divergence are associated with species differences among other fungal genera. Calculations based on the rates of change of the small subunit rRNA genes and the internal transcribed spacer (ITS) regions of the nuclear ribosomal locus estimate that these two species diverged 22–15 million years ago (Cushion et al. 2004a).

The MSG that are on the surface of all *Pneumocystis* organisms are encoded by a multigene family. MSG genes from each of the *Pneumocystis* populations in rats were found to be genetically distinct, as evidenced by the lack of hybridization of a probe from prototype to variant *Pneumocystis* populations separated by contour clamped homogeneous electrical field (CHEF) (Cushion et al. 1993) and by sequence comparisons that showed 35 percent divergence (Cushion et al. 2004a). Moreover, the genetic elements associated with regulation of the transcription of MSG genes from each of these populations were found to be quite different (Schaffzin and Stringer 2000). These genetic differences were verified at a protein level with immunoblotting techniques (Vasquez et al. 1996).

Other animals

Two *Pneumocystis* populations coinfecting ferrets have been found to vary in sequence at the *arom* locus by a similar level of divergence (15 percent) observed between *P. carinii* and *P. wakefieldiae* (Banerji et al. 1994). These

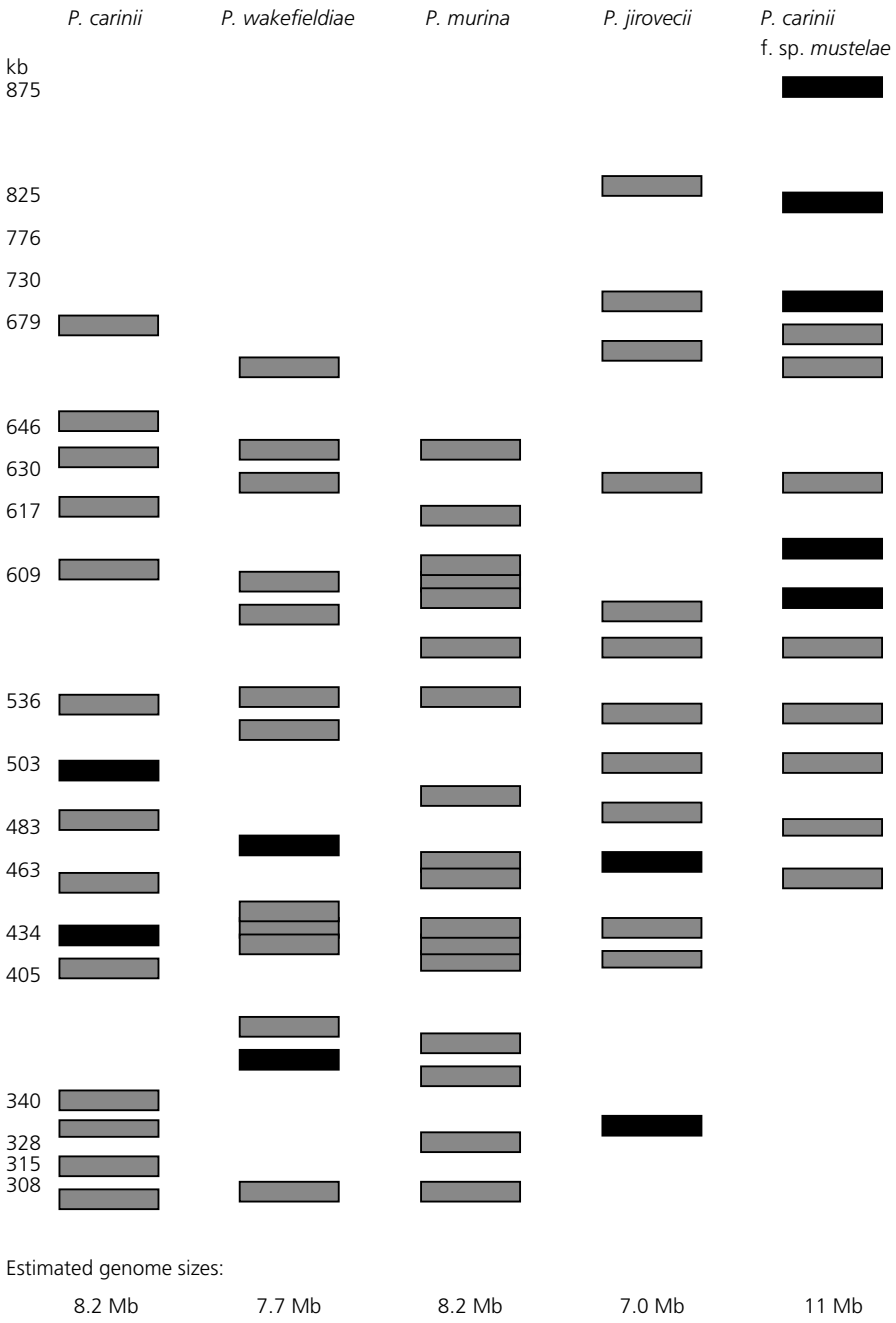

Figure 6 *Schematic of electrophoretic karyotypes from different species and putative species of* Pneumocystis. *Profiles were based on the migration of chromosome-sized bands using the pulsed field technique of CHEF. Sizes of chromosomes were calculated by linear regression using concatenated lambda phage DNA. Reprinted with permission from Cushion et al. 2004b, p. 165*

two sequences were 17 and 18 percent divergent from the *P. carinii* and *P. wakefieldiae arom* gene sequences.

PCR amplification directed to the mtLSU of *Pneumocystis* was used to amplify DNA purified from the lung tissue of a female Cavalier King Charles Spaniel diagnosed with PCP. Two sequences of about 350 bp each had 86.9 percent identity to each other and identity with other *Pneumocystis* species that ranged from 87 to 73 percent (English et al. 2001). The 13 percent divergence between the two sequences is similar to differences observed between the two rat *Pneumocystis* species (Cushion et al. 2004a), and indicates that these may be from two distinct genomes infecting the dog. Further studies of the organisms from the ferret and dog will require additional sequence data to validate these potential species.

Human *Pneumocystis*

The level of genetic divergence among *Pneumocystis* organisms infecting humans appears to be less than

Table 3 *Percentage divergence between DNA sequences of* P. carinii *and* P. wakefieldiae

that between the two species found in rats (Nimri et al. 2002). However, significantly more genotypes of *P. jirovecii* have been identified based on differences of a few nucleotides, but only one karyotypic profile has been reported for human *Pneumocystis* (Stringer et al. 1993).

A number of different genetic loci have been used to type human infections, but most studies employ the ITS of the nuclear rRNA genes, the mtLSU, and more recently, the *DHPS* gene, the target of sulfamethoxazole (Beard 2004). Use of these markers has been used to:

- show that humans can be infected by a single *P. jirovecii* genotype or mixed genotypes
- explore the distribution of genotypes among geographic locations and association of genotypes with underlying disease states
- detect the presence of potential mutations associated with drug resistance.

The ITS regions of the nuclear rRNA operon have produced the most diversity thus far. This locus in *Pneumocystis* consists of genes encoding the 18S, 5.8S, and 26S subunits. The ITS1 and ITS2 regions are located between the 18S and 5.8S, and the 5.8S and 26S genes, respectively (Liu and Leibowitz 1993). These regions evolve more rapidly than the genes that they flank and are useful for detection of differences among closely related populations of organisms (Chen et al. 2000). To date, 15 types of ITS1 sequences (types A through O) and 14 types of ITS2 sequences (a to n) have been reported, for a total (in combination) of more than 60 genotypes (Lee et al. 1998; Nimri et al. 2002). Despite dramatic geographic differences, ranging across nine countries and spanning four continents and numbering greater than 300 specimens, the most common genotype of *P. jirovecii* was 'Eg' followed by type 'Ne' (Lee et al. 1998; Nimri et al. 2002).

Four genotypes occur in the *P. jirovecii* mtLSU loci with two polymorphisms each at nucleotides 85 and 248 (Beard et al. 2000). Genotypes 1 (85:C/248:C) and 2 (85:A/248:C) were those most frequently detected in a study evaluating geographic variation among *P. jirovecii* populations, while genotypes 3 (85:T/248:C) and 4 (85:C/248:T) were found in less than 10 percent of the 324 samples analyzed (Beard et al. 2000).

Four distinct genotypes are also found in the *P. jirovecii DHPS* gene, at locations in which the same mutations conferred resistance to sulfa-based drugs in other pathogens (Skold 2000), namely (165:A/171:C), genotype 1; (165:G/171:C), genotype 2; (165:A/171:T), genotype 3; and (165:G/171:T). All these mutations are nonsynonymous, resulting in amino acid substitutions. Genotype 1 encodes a threonine at amino acid position 55 and a proline at position 57; genotype 2 has an alanine at position 55 and a proline at 57; genotype 3, a threonine at 55 and a serine at 57; and genotype 4 contains an alanine at 55 and a serine at 57. Combination of the the four genotypes of the mtLSU and the *DHPS* predicts 16 possible combinations, of which 14 have been observed (Beard et al. 2000).

New *Pneumocystis* nomenclature

In 1976, Frenkel proposed that a distinction be made between the organisms obtained from humans and those from rats on the basis of inability to cross-infect and due to serological reactivities (Frenkel 1976). The suggested names, *Pneumocystis jiroveci* for the human organism and *Pneumocystis carinii* for the one found in rats, did not gain wide acceptance.

The cumulative evidence provided by genetic data and cross-infection studies led a large group of *Pneumocystis* investigators to reconsider the issue of nomenclature at the 3rd International Workshop on *Pneumocystis*, Cleveland, Ohio, June 1994. It was the consensus of the group that sufficient evidence for speciating the organisms had not been obtained and a provisional system of nomenclature was proposed until other requirements as outlined by the Code were met to initiate species distinctions. In sexually reproducing organisms, individuals within a species are interfertile and reproductively isolated from individuals of other species. As the reproductive capacity of *Pneumocystis* is not fully understood

and the organism cannot be cultured or cloned, taxonomic hierarchy relying on historical methods may not be forthcoming. It was proposed that the organisms found in each mammalian species be given a tripartite name based on the host of origin and in accordance with the International Botanical Code of Nomenclature for 'physiological variants' (The Pneumocystis Workshop 1994; Greuter 2000). For example, the name provisionally given to *Pneumocystis* from mouse was *Pneumocystis carinii* f. sp. *muris*. Occasionally these names may still be found in the literature.

In 1999, Frenkel began the formal process required for describing new species of *Pneumcoystis* (Frenkel 1999). He retained his originally proposed name for the species found in humans, *P. jirovecii*, and the name for the most common organism found in rats as *P. carinii*. Subsequently, the other species found in rats was described and named *P. wakefieldiae* (Cushion et al. 2004a), followed by description of the species in mouse as *P. murina* (Keely et al. 2004). There are now a total of four formally described *Pneumocystis* species in the fungal phylum Ascomycota, subphylum Taphrinomycotina (O.E. Eriksson and Winka 1997), Order Pneumocystidales (O.E. Erikss. 1994), Class Pneumocystidomycetes (sensu O.E. Erikss. and Winka 1997), Family Pneumocystidaceae (O.E. Erikss. 1994), Genus *Pneumocystis* (Delanoë and Delanoë 1912) (Table 4).

These species were described using a combination of molecular and phenotypic characteristics following a phylogenetic species concept (Taylor et al. 2000) rather than standard methods of species using mating crosses. Phylogenetic analyses with neighbor-joining trees applied to five *Pneumocystis* taxa, seven *Taphrina* taxa, *S. pombe*, and *S. cerevisiae* separated the archiascomycetes (*Taphrina*) cluster from the hemiascomycete cluster (*S. pombe*, *S. cerevisiae*), with the *Pneumocystis* cluster between the two, strongly supporting monophyly for the three groups (Keely et al. 2004). Within the *Pneumocystis* group, *P. murina* forms a monophyletic clade with the other two species found in rodents, *P. carinii* and *P. wakefieldiae*, with a higher affinity for *P. carinii* (Figure 7). Based on estimates using the rDNA and *DHFR* genes as well as taking into consideration the divergence of the hosts, it appears that *P. murina* has been living in the mouse for about 30–40 million years (Keely et al. 2004), while the *Pneumocystis* group probably diversified about 100 million years ago.

Table 4 *The taxonomic hierarchy of* Pneumocystis

Class	Pneumocystidomycetes
Family	*Pneumocystidaceae*
Genus	*Pneumocystis*
Species	*jirovecii, carinii, wakefieldiae, murina*

IN VITRO PROPAGATION

The single most important need in *Pneumocystis* research is the establishment of a continuous in vitro propagation system. Since the 1940s a multitude of investigators have attempted to culture primary isolates from mammalian hosts onto various artificial substrates, monolayer and cell tissue cultures, and organ cultures, without success. Even in this new century, the ex vivo culture of any *Pneumocystis* species defies the efforts of scientists. At best, the organism is able to replicate five- to tenfold after inoculation from the host, with only a few passages of diminishing numbers (Cushion 1989). The lack of in vitro propagation has hampered basic biological studies and also more sophisticated molecular genetic techniques. Many approaches for in vitro growth have been tried, some of which are summarized here. Other reviews are recommended to the interested reader for further details (Cushion 1989; Sloand et al. 1993; Armstrong and Cushion 1994b).

Monolayer-based systems

A relatively large number of cell lines and conditions have been explored with little improvement over the tenfold increase in number of *Pneumocystis* most frequently reported (Sloand et al. 1993). Laboratories currently using tissue culture systems routinely employ the human lung epithelioid A549 cell line, the human lung fibroblast line, HEL, or the mink lung cell line, Mv 1 Lu. Growth rates are variable within a laboratory and among laboratories. The use of monolayer-based systems for in vitro drug screening remains problematic. A viability stain must be included in the organism counts over the short-term culture period; dead *Pneumocystis* can stain with Giemsa/Diff-Quik and lead to misinterpretation of a drug's effects. Certain drugs detrimentally influence the viability and metabolic processes of the monolayer cells, leading to an incorrect conclusion of efficacy for *Pneumocystis*. Evaluation of the uptake of radiolabeled precursors is also confounded by the presence of monolayer cells. Monolayer cell systems have been useful for studying the mechanisms of *Pneumocystis* adhesion (Limper et al. 1991, 1993) and should provide additional information in this area of research and other host cell–pathogen interactions.

Cell-free systems

In the late 1980s and early 1990s, a number of cell-free systems were evaluated for growth and drug-screening capabilities. An increased incorporation of [^{35}S]methionine

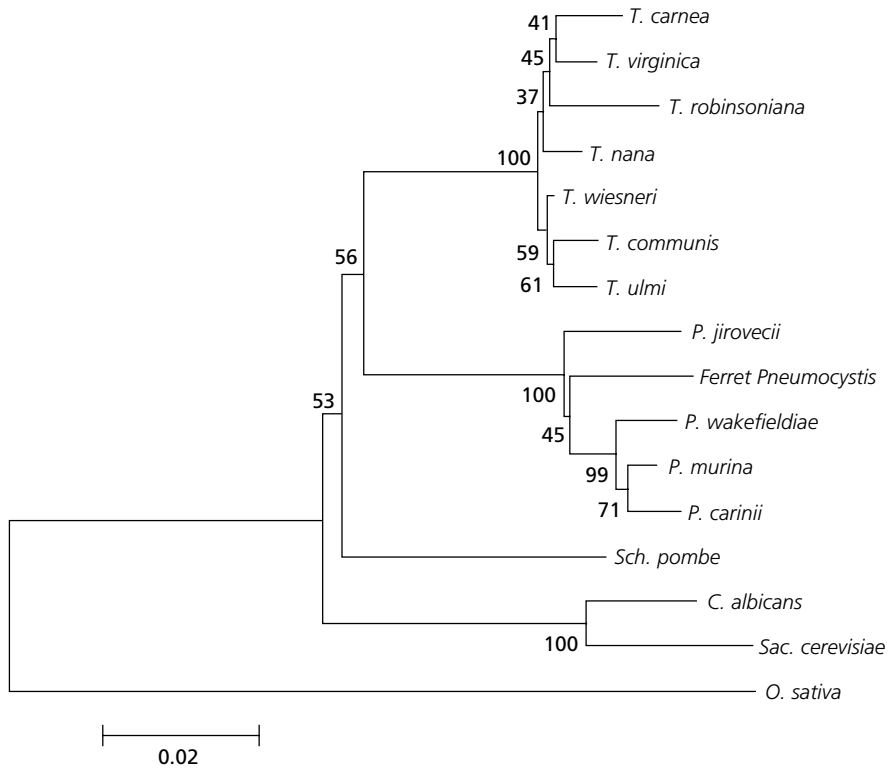

Figure 7 *Phylogenetic tree depicting the relationships between* Pneumocystis *species and among higher fungi. The tree was constructed using the neighbor-joining method, pairwise deletion, and Kimura two-parameter (K2P) in MEGA version 2.1 software (Kumar et al. 2001). One thousand bootstrap replications were performed and the values (expressed as percentages) are shown at the nodes. Bar indicates K2P distance. Reprinted with permission from Keely et al. (2004)*

into *Pneumocystis*-specific proteins over time and a five- to sevenfold increase in organism nuclei were observed in organisms maintained in a neopeptone-based medium (Cushion and Ebbets 1990). *Pneumocystis* from nude mice increased fourfold in a primary culture containing Dulbecco's MEM medium supplemented with fetal bovine serum and reducing agents (Tegoshi and Yoshida 1989). Four serial passages of declining growth were observed. Comley and Sterling (1994) used rat *Pneumocystis* to demonstrate incorporation of *para*-aminobenzoic acid (pABA) and de novo synthesis of folates in an RPMI-1640 based medium. In this system, *Pneumocystis* were most viable in the first 24 hours of ex vivo maintenance as shown by pABA uptake, but organisms that stained with Giemsa persisted throughout the 3-day culture period. Exposure to pentamidine at high levels (100 μM) resulted in a dramatic decrease in radiolabel incorporation, but not in organism number.

A cell-free system using a collagen-coated porous membrane support matrix that could maintain the continuous cultivation of *Pneumocystis* from rats was described in 1999 (Merali et al. 1999). The key ingredients included *S*-adenosylmethionine, an iron component in the form of ferric pyrophosphate, *N*-acetylglucosamine, pABA, putrescine, and horse serum. Temperature of incubation was lower than previously reported, 31°C, and the pH was higher at 8.8. The doubling times ranged from 19 to 65 hours, depending on the inocula density. The addition of *S*-adenosylmethionine was thought to be an essential component and it was later reported that *P. carinii* was auxotrophic for this compound (Merali et al. 2000). Although enthusiasm for the method was initially very high, other laboratories were unable to repeat the success of the originating laboratory (Larsen et al. 2002; Cushion and Walzer 2004).

In 1994, a cell-free system for the maintenance of *Pneumocystis* from rats using an ATP bioluminescent assay was reported (Chen and Cushion 1994a). Organisms cultured in an RPMI-based system with fetal bovine serum and nutritional additives were responsive to the standard anti-*Pneumocystis* compounds, TMP-SMX and pentamidine, and could increase modestly (three- to fivefold) over a 7-day period. Refinement of the system using a multisample luminometer permitted large numbers of compounds to be screened per year, resulting in a profile of responses to more than 60 compounds representing several classes of drugs (Cushion et al. 1997a). More recent improvements to the system include standardization of inocula by ATP content, karyotypic profile, and use of cryopreserved organisms (Collins and Cushion 2001). The latter modification reduced reliance upon availability of organisms

from the immunosuppressed animal model and permitted a series of assays to be performed with a single characterized 'lot' of organisms.

BIOCHEMISTRY AND METABOLISM

The lack of a continuous culture system has compromised metabolic studies in two significant ways. First, the veracity of the incorporation of radiolabeled precursor molecules or the identification of biochemical constituents can be difficult to interpret due to the presence of contaminating host cells that may take up the same compounds or contribute to the biomolecular pools. Second, the interpretation of results in a suboptimal in vitro environment must acknowledge the tenuous state of organisms after isolation from the mammalian lung and subsequent placement in less than adequate culture conditions. Nonetheless, investigators have persevered and the results of these biochemical analyses are summarized here.

The presence of gene homologs representing many metabolic processes has been identified by sequencing of the *P. carinii* genome and should help discern the actual metabolic capacities of these organisms(Cushion 2004a, b; Porollo et al. 2004). In this section, the potential gene homologs identified by the *Pneumocystis* Genome Project or by other laboratories belonging to metabolic cycles that have been explored by standard biochemical approaches are noted. For a more comprehensive summary of potential metabolic cycles in *Pneumocystis*, the reader is directed to the following resources: Cushion 2004a, b; Porollo et al. 2004.

General and intermediate metabolism

Early studies using standard biochemical approaches provided evidence for an operational glycolytic pathway in *Pneumocystis* (Pesanti and Cox 1981; Mazer et al. 1987; Pesanti 1989). Recent genomic data lend strong support for a typical glycolytic pathway in *P. carinii*. Homologs to fungal enzymes in the pathway found in its genome include hexokinase, phosphofructokinase, fructose-biphosphate aldolase, triose phosphate isomerase, phosphoglycerate kinase, pyruvate kinase (Porollo et al. 2004), and enolase (Fox and Smulian 2001).

Several lines of investigations indicate that *Pneumocystis* respires aerobically. The presence of intact mitochondria observed by light microscopy and at the ultrastructural level, cytochemical and electrophoretic techniques, as well as incorporation studies predict a functional tricarboxylic acid (TCA) cycle, oxidative phosphorylation, and an active electron transport chain (Pesanti and Cox 1981; Mazer et al. 1987; Pesanti 1989). Cytochrome activities were predicted by inhibition studies with cyanide (Pesanti 1984; Chen and Cushion 1994b), hydroxynaphthoquinones (Dohn and Frame 1994; Hughes et al. 1990), and antimycin A (Chen and Cushion 1994a). The synthesis of ATP was verified by direct analysis using bioluminescence detection (Chen and Cushion 1994a). Gene sequences isolated from mitochondrial DNA of *Pneumocystis* indicate that *Pneumocystis* contains the genes necessary for mitochondrial processes (Pixley et al. 1991; Cushion and Smulian 2001). *Pneumocystis* has been shown to use oxygen at a low rate, perhaps due to unfavorable assay conditions (Pesanti 1984).

All the genes necessary for a functional citric acid cycle in *P. carinii* have been identified in genomic and cDNA sequences by homology to fungal genes (Porollo et al. 2004) and include pyruvate dehydrogenase, citrate synthetase, aconitase, isocitrate dehydrogenase, alpha ketoglutarate, succinyl-coA synthetase, succinate dehydrogenase, fumarase, and malate dehydrogenase. Likewise, the various subunits of the complexes necessary for oxidative phosphorylation are present in its mitochondrial genome, including seven of the NADH dehydrogenase (complex I); the succinate dehydrogenase of complex II; cytochrome *c*–coenzyme Q oxidoreductase of complex III; cytochrome oxidase of complex IV; and the ATP synthase subunits (Porollo et al. 2004).

Sterol metabolism

Sterols are thought to be used for two purposes in fungal cells, in the maintenance of cell architecture and function of membranes and as a requirement in cellular processes: 'metabolic sterols' (Benveniste 2002). Yeast sterols are distinct from those in animal cells, with ergosterol and 24(28)-dehydroergosterol predominating in yeast membranes.

Kaneshiro and colleagues performed direct biochemical analyses that confirmed cholesterol, rather than ergosterol, was found as the most abundant bulk sterol in *Pneumocystis* preparations (Kaneshiro et al. 1989). The activity of a key enzyme in the biosynthesis of mevolonate, 3-hydroxy-3-methylglutaryl coenzyme A reductase, was detected by biochemical methods and could be inhibited by lovastatin (Kaneshiro et al. 1994a, b). Incorporation of radiolabeled squalene and mevolonate into specific *Pneumocystis* sterols provided evidence that the organism was capable of its own sterol biosynthesis (Kaneshiro et al. 1994a). Incorporation studies with radiolabeled serine, ethanolamine, and choline provided evidence that the organism could metabolize phospholipid head groups and de novo synthesize sphingolipids (Florin-Christensen et al. 1995). Furlong et al. (1994) provided chromatographic and mass spectrometry data indicating the presence of phytosterols in *Pneumocystis*-infected rat lungs and verified the earlier findings of the lack of ergosterol and cholesterol as the predominate bulk sterol.

Inhibitor studies provided evidence that at least a portion of the sterol pathway of *P. carinii* may be operational. Terbinafine, an inhibitor of squalene

epoxidase, was shown to be effective against *Pneumocystis* infections in vivo and to inhibit organism growth in vitro (Contini et al. 1994, 1996; Cirioni et al. 1995). Likewise, Urbina et al. (1997) could inhibit sterol C-24 alkylation in vitro using targeted inhibitors and subsequently decrease proliferation of the organisms in short-term culture as well as inhibit the biosynthesis of its sterols. An in vitro study utilizing the bioluminescent ATP assay was conducted to probe several enzymatic steps of the sterol biosynthetic pathway in *P. carinii* (Kaneshiro et al. 1999b). Coincident with these inhibition studies, several orthologs of the genes in this pathway were identified in gene databases generated by the *Pneumocystis* Genome Project (Porollo et al. 2004). Significantly, the inhibitory functions probed by the ATP assay could be associated with the presence of the gene in the *Pneumocystis* genome. Thus, inhibitors targeted to the enzymatic steps driven by *erg1* (squalene epoxidase), *erg7* (oxidosqualene-lanosterol cyclase), and *erg6* [*S*-adenosyl-Lmethionine:sterol C-24 methyltransferase (SAM:SMT)], resulted in decreased organism viability. The lanosterol demethylase gene of *P. carinii* was recently sequenced (Morales et al. 2003) and its presence could explain the inhibition shown by treatment with proprietary inhibitors GR 40317A, GR 42539X, and GR 40665X (Kaneshiro et al. 2000) but not with standard azoles in clinical use. The precise structure of the *P. carinii erg11* gene homolog awaits further study, but such structural information should reveal the specific properties that render it refractory to standard azoles.

Orthologs to HMG-CoA reductase 1 and 2 (Hmg1, 2, *S. cerevisiae*) genes have recently been detected in the *P. carinii* genome (Porollo et al. 2004). Although the compounds targeting this step were ineffective at reducing the ATP pools of the *P. carinii* in this study, more recent studies performed in our laboratory showed strong inhibition of ATP with the HMG-CoA reductase inhibitor, simvastatin (Collins et al. 2003). Curiously, a homolog to *erg4*, which encodes the enzyme that catalyzes the last step in ergosterol biosynthesis [the sterol C-24(28) reductase], was identified in the *P. carinii* genome (Porollo et al. 2004). Whether this genomic sequence is functional, and what role it plays, if any, in ergosterol biosynthesis, is not known at this time. Members of the genus *Pneumocystis* may not be typical fungal organisms due to the lack of ergosterol as their major sterol, but these organisms still have a functional sterol biosynthetic pathway that can be exploited for drug development.

A rare C_{32} sterol, the C-24-alkylated lanosterol derivative 24(*Z*)-ethylidinelanost-8,24(28)-3β-ol, was detected in large amounts in *P. jirovecii* (Kaneshiro et al. 1999a). Given the trivial name, pneumocysterol, this compound was reported to comprise almost 50 percent of the organism-specific sterols in some samples derived from human lungs. Although present in other *Pneumocystis* species, pneumocysterol appears to be most abundant in human organisms.

As a direct result of the *Pneumocystis* Genome Project, genes associated with sterol biosynthesis encoding *erg7* (AF285825) and *erg6* (AY032981) (Kaneshiro et al. 2001a; Zhou et al. 2002), were sequenced. The *erg6* gene of *P. carinii* was cloned, expressed in *Escherichia coli*, and was able to complement the null mutant in *S. cerevisiae* (Kaneshiro et al. 2001a). The sterol-binding motif of the *P. carinii* SAM:SMT product was novel and reported to have high-affinity binding properties of lanosterol. Furthermore, the enzyme was able to transfer methyl groups from *S*-adenosyl-L-methionine (SAM) to the C-24 position of both lanosterol and 24-methylenelanosterol, thus defining it as an enzyme capable of two methyl group transfers (Kaneshiro et al. 2001a). The oxidosqualene cyclase (Erg7p) encoded by the *ERG7* gene converts oxidosqualene to lanosterol, the first cyclic component of sterol biosynthesis.

The isoprenoid biosynthetic pathway leading to the production of squalene and other compounds includes a branch giving rise to the polyprenyl chain of coenzyme Q (ubiquinone). Coenzyme Q homologs function in the mitochondrial electron transport chain and offer a potential drug target in some parasite–host situations. Kaneshiro et al. (1994b) identified the homolog CoQ_{10} as the predominant species in *Pneumocystis*-infected lung homogenates and further showed that the ubiquinone could be de novo synthesized by incorporation of radiolabeled mevalonic acid into the molecule. Most higher animals contain CoQ_{10} as the sole endogenous ubiquinone, except in the rat, where CoQ_9 is the major homolog (Ellis 1994). Coenzyme Q analogs that function as antiparasitic drugs include the 8-aminoquinolones and hydroxynapthoquinones. Atovaquone, a hydroxynapthoquinone which is used for the treatment of moderate PCP, is an analog of coenzyme Q and blocks mitochondrial electron transport by binding to cytochrome *b* of the bc_1 complex (Gutteridge 1991). In addition, atovaquone was recently reported to inhibit *P. carinii* coenzyme Q biosynthesis (Cushion et al. 2000; Kaneshiro et al. 2001b).

FATTY ACIDS

Pneumocystis lives in an environment in which it is bathed in lipids comprising mainly saturated fatty acids. Purified preparations of *Pneumocystis* have been shown to take up the radiolabeled and fluorescently labeled fatty acids oleic, linoleic, palmitic, stearic acids, and phospholipids (Paulsrud and Queener 1994; Sleight et al. 1994). An epoxy fatty acid, *cis*-9,10-epoxyoctadecanoic acid (epoxy stearate), was identified in purified *Pneumocystis* preparations (Ellis et al. 1994). This unusual fatty acid has been detected in rust fungi where it is a major component. It is interesting to note that like *Pneumocystis*, the rust fungi also lack ergosterol.

Transport

Little is known of the transport or efflux systems of *Pneumocystis*, but these functions are likely important in determining the efficacy of therapeutic compounds. Studies to identify mechanisms of amino acid and glucose uptake were recently conducted (Basselin-Eiweida et al. 2001). Simple diffusion was found as the mechanism for translocation of aspartic acid. By contrast, Michaelis–Menten first-order kinetics, indicating the presence of carrier-mediated mechanisms, was exhibited by the neutral amino acids glutamine, leucine, and serine; the basic amino acid arginine; and the aromatic amino acid tyrosine. Leucine, glutamine, and serine used the same carrier system, as illustrated by competition assays. Exogenous glucose was necessary for efficient amino acid uptake, while other sugars, e.g. galactose, fructose, were less effective. Neutral, basic, and aromatic acids alike were taken up by facilitated diffusion. This conclusion was drawn from observations regarding the effects on uptake with reduced sodium or potassium ions; the lack of inhibition of transport by oubain and valinomycin; and the lack of effect when inhibitors to ATP synthesis and maintenance of the electrochemical ion gradients and membrane potentials were added to the assay. Transport of arginine appeared to be facilitated by both a high-affinity carrier and a low-affinity carrier. In addition, *P. carinii* may possess a separate carrier for aromatic amino acids that may also transport neutral amino acids.

Transport of glucose, and the inhibitor, 2-deoxyglucose, utilized two facilitated transport systems (Basselin-Eiweida et al. 2001). The high-affinity transporter was inhibited by protein synthesis inhibitors, suggesting active transport. The properties of the low-affinity system indicated it was likely to operate by facilitated diffusion, probably in environments of high exogenous glucose levels. Importantly, these investigators noted the dramatically slow uptake rate of both amino acids and glucose by *P. carinii*. They conjectured that *P. carinii* may be capable of synthesizing most of these compounds, negating the requirements for high-affinity transporters or such mechanisms.

Polyamines

Polyamines are low molecular weight polycations thought to play an important role in the regulation of cell growth and differentiation (McCann et al. 1986). *Pneumocystis* appear to have functional polyamine biosynthesis (Merali and Clarkson 1996). However, they are unable to regulate polyamine catabolism as a result of uncontrolled activity of the key enzyme spermidine/spermine-N^1-acetyltransferase (SSAT) (Merali 1999). This results in a net loss of polyamines from the cell and back conversion to smaller polyamines which could make it vulnerable to compounds that interfere with polyamine biosynthesis. α-Difluoromethylornithine (DFMO) is an irreversible inhibitor of the first and rate-limiting step in polyamine biosynthesis, the conversion of ornithine to putrescine by the enzyme ornithine decarboxylase. This compound was effective in reducing *Pneumocystis* infection in immunosuppressed rats in one laboratory (Clarkson et al. 1990) but not in another (Walzer 1994). Ornithine decarboxylase activity was not detected in an early study by Pesanti et al. (1988), but later, Clarkson et al. (1990) reported measurable activity. To date, a fungal homolog for the gene encoding ornithine decarboxylase has not been identified in the EST library or the genome of *P. carinii*, but the gene encoding an inhibitor of the enzyme ornithine decarboxylase antizyme has been detected in the EST and genomic libraries (Ivanov et al. 2000; Porollo et al. 2004).

S-Adenosylmethionine (AdoMet) is a key molecule in both methylation reactions and polyamine biosynthesis. Most AdoMet is used for transmethylation reactions which transfer the *N*-methyl group of the methionine group to other molecules such as proteins, lipids, or DNA which forms new molecules in some cases (e.g. lecithin in the case of complex lipids), or regenerates the methionine. The remaining AdoMet (~2–5 percent) enters into polyamine biosynthesis after decarboxylation (Merali et al. 2000). AdoMet synthetase transfers the adenosyl group of ATP to methionine to form AdoMet and release of P_i and PP_i. Recently, it was reported that the long-term culture of *P. carinii* was dependent upon exogenous supplementation of AdoMet (Merali et al. 1999). Further studies by these investigators described the lack of AdoMet synthetase activity by *P. carinii* in an in vitro system and characterized two transporters, one high affinity and one low affinity, that were capable of transporting exogenous AdoMet into the cells (Merali et al. 2000). They concluded that *P. carinii* was auxotrophic for AdoMet, a finding unprecedented in the fungal kingdom. Supporting their discovery was the apparent reduction of plasma AdoMet concentration in *P. carinii*-infected rats that was correlated with infection burden (Merali et al. 2000). Translation of the effect to the clinical setting confirmed the reduction of plasma AdoMet in patients suffering from PCP, but not in those with bacterial pneumonia, tuberculosis, or cryptococcal meningitis (Skelly et al. 2003). These findings are very intriguing and demand further investigation. On the one hand, replication of the success reported by the authors of these studies using a culture supplemented with AdoMet has not been reproduced in other laboratories (Cushion and Beck 2001; Larsen et al. 2002) and the presence of a fungal gene homolog encoding AdoMet synthetase in the genome of *P. carinii* also seems to contradict the assertion that the organism does not have the capacity to synthesize AdoMet (Porollo et al. 2004).

However, expression of the gene has not been verified and the clinical and experimental findings of plasma AdoMet depletion in infected hosts lends support for the salvage of this compound by these organisms.

Replication

Thermal denaturation studies and gene sequence data show the genome of rat-derived *Pneumocystis* to be adenine and thymine rich (Stringer and Cushion 1998). These initial findings have been supported by the sequencing of over 3 000 genes by the *Pneumocystis* Genome Project. The current estimate of genome-wide A+T content is ~70 percent.

The ploidy of the *Pneumocystis* genome has not been definitively defined. Cytofluorometric evaluations of cyst and trophic forms using the DNA-intercalating stain 4′,6-diamidino-2-phenylindole (DAPI) indicated that 90 percent of the trophic forms contained the same DNA content as those within the cyst (Yamada et al. 1986). Later studies using a number of nuclear intercalating dyes and image analysis confirmed the apparent haploid state of the trophic forms and ascospores within the cysts (Wyder et al. 1994); however, there was some variation observed in the nuclear content, suggesting that there may be other states of ploidy. By contrast, two-dimensional separation of apparently homologous chromosomes by pulsed-field gel-separated chromosomes predicted a diploid nucleus (Cornillot et al. 2002).

There are conflicting data on the incorporation of precursors into *Pneumocystis* nucleic acids. One early study found organisms sustained in a balanced salt solution could incorporate [^{3}H]uridine into TCA-precipitable material, although the uptake was not inhibited by the anti-*Pneumocystis* drug pentamidine (Pesanti and Cox 1981). These investigators reported no uptake of radiolabeled thymidine or hypoxanthine. By contrast, organisms incubated in a low pH minimal medium were able to incorporate [^{3}H]uridine, uracil, thymidine, and hypoxanthine as well as [^{35}S]methionine (Cushion and Ebbets 1990). More recently, the ability of *Pneumocystis* to incorporate 5-bromodeoxyuridine in the lungs of rats and mice was evaluated to determine whether a salvage pathway for thymidine was operational (Vestereng and Kovacs 2004). No incorporation was observed by either *P. murina* or *P. carinii*, although host cells readily took up the analog, suggesting that if *Pneumocystis* possesses a thymidine salvage pathway it was not active during infection in the mammalian host.

Analysis of a partial EST database from *P. carinii* revealed about 11 percent of the genes identified as fungal homologs were associated with the transcription process, including initiation factors, regulators, repressors, terminators, chromatin remodeling proteins, and histone proteins and regulators (Cushion et al. 2004b; Porollo et al. 2004). In addition, sequencing of its genome revealed a multitude of fungal homologs to DNA repair genes such as *rad2*, *rad8*, *rad15*, *rad16*, *rad18*, *rad26*, *rad32*, and *rad50*; repair helicases *rhp26*, *rhp54*, and *rhp57*; and *MSH2* (Porollo et al. 2004).

Carbohydrates

Besides the chromoatographic analyses of monomeric sugars in the cell wall of *Pneumocystis*, described above, other studies suggest the presence of more complex carbohydrate polymers. The lytic action of the enzyme preparation, Zymolyase, which contains as its major component β-1,3-glucan laminaripentaohydrolase, and the staining of the cyst wall with aniline blue suggest the organism maintains a glucan layer, at least in the cyst form. The gene encoding the *P. carinii* β-1,3-glucan synthetase gene *Gsc1* was cloned and shown to mediate the polymerization of uridine 5′-diphosphoglucose into β-1,3-glucan (Kottom and Limper 1999, 2000). The glucan in the cyst wall of *Pneumocystis* was implicated as a factor in the detrimental inflammatory response in the lungs of its mammalian hosts (Hahn et al. 2003). Compounds targeting glucan synthesis were found to arrest the replication of cysts in the lungs of treated animals and offer an attractive alternative target for chemotherapy of infection (Schmatz et al. 1990, 1995). In addition to β-glucan, direct synthesis of α-1,4-glucan in short-term culture was shown by biochemical methods, GC-MS, and uptake experiments (Williams et al. 1991). α-Glucan in the cell wall plays a key role in fission yeast morphogenesis, maintenance of the characteristic cylindrical shape, and separation of the mother and daughter cell after mitotic replication (Konomi et al. 2003).

PNEUMOCYSTIS INFECTION

Incidence of PCP

In the pre-AIDS era, defined as those decades prior to 1980, the number of reported cases of PCP in humans was fewer than 100 (Walzer et al. 1974; Kovacs et al. 2001). In the decades that followed, a dramatic increase in cases was observed due to the onset of the AIDS epidemic in 1982. In 1991, the incidence of PCP peaked at 20 000 cases, with a subsequent decline due to the recommendation for prophylaxis of HIV-positive patients with a CD4 cell count of less than 200/μL from a Public Health Service task (1989). This decline was even more dramatic after 1995 when widespread HAART was instituted, targeting the HIV virus and permitting immune reconstitution of patients (Kaplan et al. 2000). After 1995, PCP declined at an average of 21.5 percent per year (Kovacs et al. 2001). In spite of such dramatic decreases in PCP cases, this pneumonia still remains the most common life-threatening infection associated with HIV-infected persons. Of significant

concern is the increasing incidence of mutations in genes targeted by the mainstays of therapy, TMP-SMX and other secondary therapies such as atovaquone.

Description of clinical features

RISK FACTORS

A decrease in cell-mediated immunity is the single most important risk factor for the development of PCP. Reduction in the cellular immune response can be potentiated by:

- administration of immunosuppressive agents, such as corticosteroids or cancer chemotherapeutic agents
- congenital conditions like the severe combined immunodeficiency disease syndrome (SCIDS)
- starvation or malnutrition
- most recently, infection with the human immunodeficiency virus (HIV).

Quantification of the number of circulating CD4+ lymphocytes has long been recognized as an indicator of the level of immunosuppression and of the risk of developing pneumocystosis (Masur et al. 1989; Phair et al. 1990). Coordination of large center studies (Multicenter AIDS Cohort Study and Pulmonary Complications of HIV Infection Study) determined that the risk for *P. carinii* pneumonia sharply increases when the CD4+ lymphocyte counts reach 200/μL in individuals not on a prophylactic regimen, while in those with less than 200/μL, the risk becomes five times greater as compared with patients maintaining counts above 200/μL.

Although depression of cell-mediated immunity is clearly a risk factor in the development of PCP, there are clinical and experimental data implicating a role for humoral immunity. Patients with only B-lymphocyte abnormalities and mice with B-cell defects have been reported to develop PCP (Saulsbury et al. 1979; Rao and Gelfand 1983; Marcotte et al. 1996) while passive antibody administration aids in the clearance of the infection in experimental animal models (Gigliotti and Hughes 1988; Roths and Sidman 1993; Gigliotti et al. 2002).

CLINICAL PRESENTATION

Adults

PCP in adults commonly presents with increasing dyspnea, a nonproductive cough, inability to breathe deeply, substernal tightness, and often with night sweats. A fever of 38.5°C and tachypnea are often encountered. Rarely, there is sputum production or hemoptysis. Physical examination of the lungs may find little deviation from normal, but various degrees of respiratory distress, small respiratory volumes and fine basilar rales may be present. AIDS patients have a more insidious progression to clinical disease than patients with immune depression unrelated to HIV, approximately 25 days versus 5–10 days (Dohn and Frame 1994).

The chest radiograph may appear normal or indicative of severe disease. Subsequent follow-up of normal radiographs by high-resolution computed tomography (CT) scan of the chest will show a ground glass attenuation if PCP is present (Gruden et al. 1997). Diffuse, symmetric interstitial infiltrates are most commonly encountered, while focal infiltrates, lobar consolidations, cavities, and nodules are less common. In early infection, the infiltrates may be widely distributed but consolidation and air bronchograms develop with progression of the disease. Increased incidence of apical infiltrates and pneumothoraces have been associated with aerosolized prophylactic pentamidine administration (Stansell and Hopewell 1995). Pneumatoceles have been observed with increasing frequency in cases of prolonged PCP (Stansell and Hopewell 1995). The degree and severity of abnormalities on the chest radiograph are prognostic and can be correlated with higher mortality.

Impaired oxygenation is the primary abnormality detected by laboratory methods (Walzer 2004b). Many patients exhibit a widening of the alveolar–arterial oxygen gradient (A–a/D_{O_2}) proportional to the severity of disease and respiratory alkalosis (Forrest et al. 1999). However, a significant number of patients can present with a normal (A–a)D_{O_2} gradient at rest. Other physiological changes include hypoxemia, impaired diffusing capacity, alterations in lung compliance, total lung capacity, and vital capacity (Walzer 2004b). Analyses of bronchoalveolar lavage fluids (BALF) have revealed a generalized fall in surfactant phospholipids and phosphatidylcholine, but an increase in surfactant proteins (SP) A and D and sphingomyelin has been observed (Phelps and Rose 1991; Hoffman et al. 1992; Limper et al. 1994; Mason et al. 1998; Martin and Wright 1999). SP-A appears to inhibit phagocytosis of *Pneumocystis* (Koziel et al. 1998b) in some studies, while in others, it was shown to mediate binding (McCormack et al. 1997). SP-D has also been shown to bind to the organism's surface glycoproteins and facilitate adherence to macrophages (Limper et al. 1995; O'Riordan et al. 1995).

Children

The presentation in children usually involves cyanosis, flaring of the nasal alae, mild cough usually without fever, and intercostal retractions in severe disease (Walzer 2004b). In contrast to increased risk of the pneumonia in adults with CD4+ counts of 200/μL or below, 27 percent of children 1 year of age or less who developed *Pneumocystis* had CD4+ counts greater than 1000/μL (Anonymous 1995), due to the higher overall CD4 count in children.

EXTRAPULMONARY PNEUMOCYSTOSIS

Prior to the AIDS era, reports of extrapulmonary spread of *Pneumocystis* were rare (Telzak et al. 1990; Ng et al.

1997). Although an incidence of 1–3 percent of extrapulmonary cases has been reported in the post-AIDS era, it is likely there are a significant number of cases that go unreported.

Most extrapulmonary *Pneumocystis* is detected as an incidental finding during postmortem examination. It is rarely considered as a cause of the clinical manifestations associated with the HIV syndrome. Extrapulmonary spread of *Pneumocystis* is found most commonly in patients in the late stages of AIDS who have not received prophylactic treatment or only aerosolized pentamidine (Walzer 2004b).

The frequency of involvement in organs other than the lungs or body sites in a series of 52 patients, 40 of whom were HIV positive and 12 who were not infected, was lymph nodes (44 percent); spleen (33 percent); liver (31 percent); bone marrow (33 percent); adrenal glands (19 percent); gastrointestinal tract (19 percent); genitourinary tract (17 percent); thyroid (17 percent); heart (15 percent); pancreas (13 percent); eyes (12 percent); ears (12 percent); skin (4 percent); and other sites (2–3 percent) (Telzak and Armstrong 1994). The incidence of *Pneumocystis* in extrapulmonary sites in HIV-positive patients was evenly distributed at about 33 percent among the lymph nodes, spleen, liver, and bone marrow. By contrast, the preferential site for extrapulmonary *Pneumocystis* in non-AIDS patients was the lymph nodes with 75 percent of the 12 patients showing involvement. Infection of multiple extrapulmonary sites has been associated with a rapidly fatal outcome. Areas of focal involvement present as retinal cotton wool spots; polyploid lesions in the external auditory canal; thyroid mass; pancytopenia from bone marrow necrosis; pleural effusion; and numerous hypodense low attenuation lesions in the spleen or other organs on CT scans. Involvement of pleural and peritoneal spaces often resulted in calcification of these surfaces. Histopathological findings of fine needle aspirates or biopsies of these lesions showed areas of necrosis with exudative foamy material. Staining with methenamine silver or fluorescently labeled monoclonal antibodies revealed characteristic *Pneumocystis* morphologies (Walzer 2004b).

PCP IN PATIENTS WITHOUT UNDERLYING IMMUNOSUPPRESSION

PCP has been rarely reported in individuals with intact immune systems. However, two reports describe the infection in the elderly. In the first, a 67-year-old man presented with tachypnea, chills, and fever (Ludmerer and Kissane 1991). The chest radiograph showed bilateral pulmonary infiltrates and a biopsy confirmed the diagnosis of PCP. No evidence of an underlying immunosuppression was detected in laboratory tests. In the second report, a cluster of five elderly patients (ages 66–78 years) presented during a 3-month period at the New York Hospital–Cornell Medical Center with somewhat atypical symptoms of *P. carinii* pneumonia (Jacobs et al. 1991). Only two had fever and the chest radiographs revealed focal, lobar infiltrates or pleural effusions rather than bilateral involvement. No obvious immune impairment was detected, although it was suggested that subtle decreases in immune function associated with age may predispose the elderly population to this infection.

Autopsy studies conducted on individuals without predisposing immune suppression showed little evidence for infection with *P. jirovecii*, either by standard histological methods (Cushion 2004c) or by use of PCR (Peters et al. 1992). However, limited sample population numbers and the small amounts of lung tissue analyzed could explain these negative results.

More recent studies employing nested PCR for detection of *P. jirovecii* in bronchoalveolar fluids or oropharyngeal washes have reported positive amplicons from patients without underlying disease as well as from patients with a wide variety of disease states not including infection with HIV (reviewed by Cushion 2004c). The accumulating evidence from these studies suggests that colonization of humans by *P. jirovecii* is not a rare event and some subpopulations may serve as reservoirs of the infection (discussed in the section on Epidemiology below).

Pathology and pathogenesis

In the advanced diffuse form of pneumocystosis, all lobes of the lung are involved. They manifest a rubbery consistency, are bulky and densely consolidated. The cut surfaces appear yellowish to reddish gray, are granular and dry with destruction of air spaces. In less severe disease, there are foci of consolidation and areas of atelectasis admixed with compensatory hyperinflation. The nodular form of pneumocystosis is rare and typified by solitary and multiple nodules with some cavitation (Walzer et al. 1989).

Histopathological examination reveals two characteristic traits:

- alveolar interstitial thickening
- a frothy eosinophilic honeycombed exudate in the lumens (Figure 8a).

The interstitial thickening is due to hyperplasia and hypertrophy of the type II pneumocytes, interstitial edema, mononuclear cell infiltration, and in some cases, mild fibrosis (Walzer et al. 1989). The cellular infiltrates are limited in the alveolar septa but more apparent in the perivascular and peribronchial regions. The honeycomb exudate usually contains organisms when stained with methenamine silver to visualize the cyst form. Organisms cannot be visualized with hematoxylin and eosin. As the disease progresses, there may be hyaline membrane formation accompanied by interstitial fibrosis and edema. Histopathological assessment of the disease in AIDS and non-AIDS patients revealed a higher organism burden but less tissue damage in the former

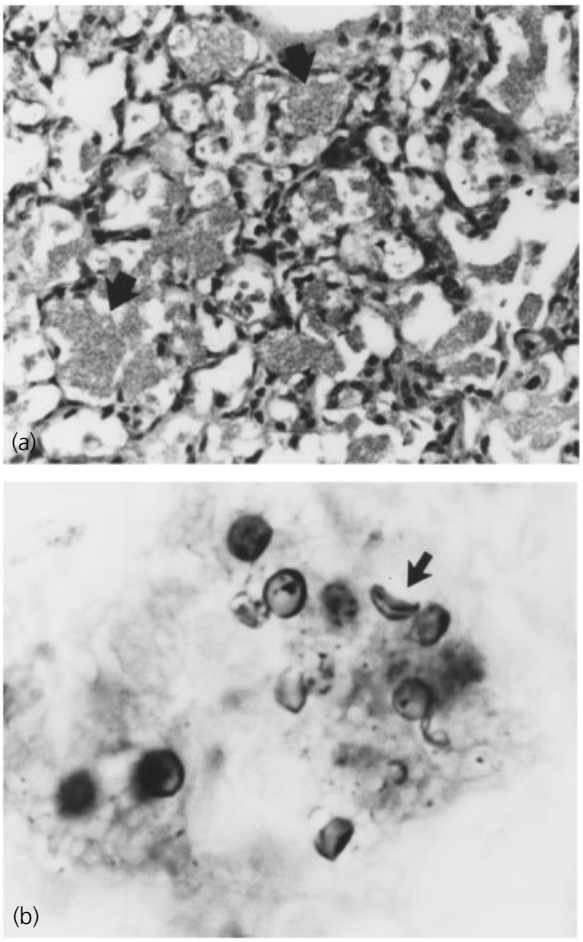

Figure 8 *Diagnostic histopathology.* **(a)** *Hematoxylin and eosin-stained lung sections. Note the characteristic honeycombed exudate, a hallmark of fulminant* P. carinii *pneumonia. (Original magnification 100×)* **(b)** *Cup-shape morphology of cysts (spore cases) visualized by Grocott's methenamine silver staining. patient group (Dohn and Frame 1994). In some patients, the alveolar exudate may not be present or microcalcifications, granulomas, or cavitary lesions instead may appear. Ultrastructural studies have detected alveolar-capillary leakage and type I cell damage associated with attachment and presence of the organism (Yoneda and Walzer 1980).

Diagnosis

PCP should be considered in any immunocompromised patient who presents with fever, respiratory symptoms, or infiltrates on chest radiogram. Because these symptoms can be associated with a multitude of infectious and non-infectious conditions, definitive diagnosis must be made by morphological or histopathological demonstration of the organism. An algorithm for evaluation of patients with suspected PCP has been published by the National Institutes of Health in 2001 (Kovacs et al. 2001) and remains a helpful guide in establishing a diagnosis and for initiation of treatment (Figure 9). This algorithm includes screening with a non-invasive sampling method, induced sputum. It is likely an updated algorithm will be issued in which alternative non-invasive techniques such as oral washes or oral swabs will be usd for DNA extraction and subsequent amplification by PCR.

Patients with a clinical presentation consistent with PCP and with a chest radiograph demonstrating reticular or granular infiltrate can be placed on therapy immediately or the diagnosis confirmed with a procedure to collect respiratory secretions for microscopic evaluation. Those with a negative chest radiograph with a high degree of suspicion should undergo additional tests.

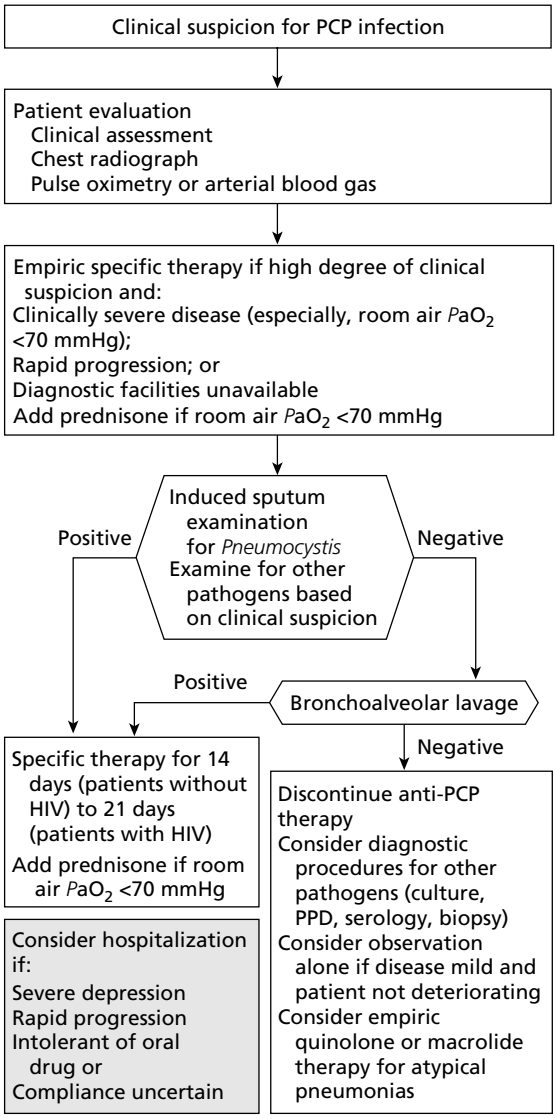

Figure 9 *Algorithm for evaluation of patients with suspected* Pneumocystis *pneumonia. Reprinted with permission from Kovacs et al. (2001)*

High-resolution CT scan of the chest or pulmonary function can be used to identify patients without the infection (Huang 2004; Walzer 2004b).

METHOD OF SAMPLE COLLECTION

The diagnosis of pneumocystosis relies on efficient sampling of the infected area. The organism can be detected in a variety of respiratory and other samples including induced sputum, BALF, tracheal aspirate fluid, tissue obtained by transbronchial biopsy, bronchial brushes, pleural fluid, oropharyngeal washes, and swabs. Generally, samples collected from HIV-infected patients provide a higher diagnostic yield than non-HIV-infected patients because of their increased organism burden.

Open thorax lung biopsy and transbronchial biopsy

Open thorax lung biopsy is the most invasive of the sampling procedures and requires the use of an operating room and general anesthesia. Fiberoptic bronchoscopy is the most common invasive procedure for collection of diagnostic tissue, but like open thorax lung biopsy, is rarely performed today. These procedures may be indicated after nondiagnostic bronchoscopy, suspicion of an infection concomitant with pneumocystosis, or for diagnosis of Kaposi's sarcoma.

Bronchoalveolar lavage (BAL)

BAL alone is more efficacious than brushings or washings, carries little morbidity, and has become the method of collection in most institutions. Sensitivity can be increased if multiple lobes are sampled and combined (Baughman 1994; Baughman et al. 1994; Walzer 2004b). Twenty to thirty milliliters of the lavage fluid is collected and concentrated by centrifugation. The pellet is smeared onto glass slides for fixation followed by histochemical staining.

Induced sputum

Deep inhalation of a 3 percent sodium chloride solution by the patient results in osmotic accumulation of fluid in and irritation of the respiratory passages, which can improve the organism yield, especially in AIDS patients. Depending on the institution, the patient base, and technical expertise, the diagnostic yield can range from 50 to 90 percent (Kroe et al. 1997; Caliendo et al. 1998). There are many fine technical points that must be considered during the procedure to provide the best diagnostic yield, including the use of toothpaste, which should be avoided, and the use of mucolytic agents to liquefy the sample (Cushion 2003). Although the procedure is non-invasive and relatively inexpensive, drawbacks to its use are the lack of information concerning other infections or disease processes that may be present in the lung and low diagnostic yield in non-AIDS patients.

Nasopharyngeal aspirates

Recent studies with neonates have increased the popularity of this sampling method (Vargas et al. 2001, 2003). Detection of *P. jirovecii* from these samples relies mostly on amplification of its DNA by PCR, but in some cases organisms have been detected (Vargas et al. 2001). An advantage of the procedure is that these samples are commonly used for diagnosis of repiratory viruses and can concomitantly be evaluated for the presence of *P. jirovecii*. The aspirates are collected with a suction catheter after instillation of 1–1.5 mL of nonbacteriostatic saline (pH 7.0) in each nostril. The sample can then be treated with a mucolytic agent and subsequently stained or prepared for the PCR by DNA extraction

MICROSCOPIC IDENTIFICATION

A variety of stains can be employed for the detection of *Pneumocystis*. Variations of the methenamine silver stain (e.g. Grocott's, Gomori's) are the most widely used for diagnosis with tissue sections, but can also be used with body fluids such as BALF. A positive reaction results in a distinctive black cup-shaped morphology of the cysts against green-colored host cell architecture (Figure 8b) (Cushion 2003). In some reactions, the cysts will appear with a darkened structure resembling a 'double comma,' or 'parentheses' within the cyst. There is no budding associated with *Pneumocystis*, and this feature can be used to differentiate *Pneumocystis* infection from other respiratory fungal diseases such as histoplasmosis. Only the cyst form of the organism can be visualized with these stains, which is a drawback to their use. If the trophic form predominates in an infection, the organism burden can be greatly underestimated. The silver stain and other stains that selectively stain the wall of *Pneumocystis* cysts (e.g. toluidine blue O, cresyl echt violet) are favored among pathologists because they provide a sharp contrast between background host cells and organism. The Papanicolaou stain, frequently used for staining cytopathological specimens, can demonstrate the foamy exudate surrounding the organisms, although the organisms stain poorly. Likewise, the gram stain produces a negative reaction with poorly defined organism morphology.

Most laboratories now use rapid variants of the Giemsa stain for accelerated diagnoses. The most rapid modification of the methenamine silver stain takes approximately 30 minutes to perform, while the rapid Giemsa-like stains (e.g. Diff-Quik^{R}, LeukoStat^{R}) take 30 seconds (Cushion et al. 1985). With the Giemsa stains, all forms of the organism are stained, which permits rapid assessment of the total organism burden. The nuclei appear reddish-purple in contrast to the light blue cytoplasm. The cyst wall excludes the dyes and appears

as a circumscribed clear zone around the cyst contents. This stain not only permits visualization of all forms of *Pneumocystis*, but also permits assessment of the sample quality by demonstration of host cells such as alveolar macrophages and neutrophils.

Commercial kits employing fluoresceinated monoclonal antibodies against surface antigens of both cyst and trophic forms are widely used for diagnosis. Although laboratories must be equipped with epifluorescent microscopes, the reaction is specific for the organism and usually can be readily visualized against the background host cells. Depending on the monoclonal antibody supplied with the kit, staining may target only the cyst form or may target all forms of the organism. Since trophic forms are more numerous than cyst forms, it is recommended that laboratories use kits with antibodies directed to all forms of the organism, such as 2G2 or 3F6, which are available from DAKO Corp., Carpinteria, CA and Chemicon International, Inc. (Kovacs et al. 2001). Fluorescein isothionate is the typical fluorophore conjugated to the antibody in a direct assay, or to the detection antibody in an indirect assay. Organisms appear a brilliant apple green in color. Immunohistochemical techniques employing antibodies specific for *Pneumocystis* have been used with success with tissue sections, although silver stains can often provide the same information. Immunohistochemistry, however, provides confirmation of diagnosis in unusual settings such as extrapulmonary pneumocystosis.

CULTURE

Detection of *Pneumocystis* by amplification using artificial media or tissue culture is not an option since there is no continuous in vitro culture system for *Pneumocystis*.

SERUM TESTS

Serum antibody detection has had little success in the diagnosis of pneumocystosis in immunocompromised patient populations (Walzer and Cushion 1989). The high prevalence of circulating anti-*P. carinii* antibodies in the general population has confounded attempts to establish a serodiagnostic test. Prior exposure to the organism cannot be distinguished from active disease.

Other serological tests sometimes used for diagnosis are similarly nonspecific. Serum lactic dehydrogenase (LDH) levels are often elevated in PCP and decline with successful treatment. However, similar increases can be associated with other diseases (Benson et al. 1991) and thus, LDH levels must be used in concert with other diagnostic modalities.

OTHER LABORATORY TESTS

Several other diagnostic tools have been used for diagnosis of PCP. Arterial blood gas (ABG) is an important laboratory test for PCP patients, due to the frequency of impaired gas exchange. Typically, patients with PCP will have a decreased arterial oxygen tension with an increased arterial–alveolar gradient, and respiratory alkalosis. The ABG can be used to direct decisions regarding patient admissions, administration of adjunctive corticosteroids, and to assess PCP therapy (Huang 2004). Gallium scans and diethylenetriamine pentaacetic scans are imaging techniques reported to be abnormal in patients with PCP, but again, are nonspecific for PCP (Huang 2004).

Pulmonary function tests are useful in those patients where there is a clinical suspicion for PCP, but in which there is a normal chest radiograph (Huang 2004). Patients with PCP will often demonstrate a restrictive ventilatory defect with decreased lung volumes and increased airflows. Measurement of the diffusing capacity for carbon monoxide, DL_{CO}, is a sensitive indicator of alveolar-capillary block (Sankary et al. 1988). In patients with PCP, this is decreased on average from 89 to 100 percent (Coleman et al. 1984; Hopewell and Luce 1985; Shaw et al. 1988; Camus et al. 1993). Although such decreases are not definitive, a normal DL_{CO} would strongly suggest the absence of PCP.

MOLECULAR METHODS

Amplification of *Pneumocystis* DNA by PCR offers a dramatically increased level of detection and the ability to genotype the infecting organism populations. Although it is not yet routinely used in the clinical laboratory, it will likely eclipse standard microscopic methods because of its specificity, sensitivity, and relative low cost. In addition to diagnosis, PCR is routinely used for investigations of colonization in normal populations and those with underlying disease states (Helweg-Larsen et al. 2002; Huang et al. 2003; Morris et al. 2004).

P. jirovecii is routinely detected in DNA extracted from human samples by PCR using primers targeting the mtLSU (Wakefield et al. 1990b). These primers are: pAZ102-E (5′-GATGGCTGTTTCCAAGCCCA-3′) and pAZ102-H (5′-GTGTACGTTGCAAAGTACTC-3′) and result in a product of 346 bp. The mtLSU gene is present in multiple copies per organism and provides the most sensitive target for detection. The reaction can be a direct one, or nested, using a second set of primers directed to a region within the product of pAZ102-E and pAZ102-H (Wakefield et al. 1990a). The internal primers are: pAZ102-X (5′-GTGAAATA-CAAATCGGACTAGG-3′) and pAZ102-Y (5′-TCAC-TTAATATTAATTGGGGAGC-3′), which produce a 267 bp product(Vargas et al. 2000). The nested approach is used for samples with anticipated low template levels.

TREATMENT

Trimethoprim-sulfamethoxazole (TMP-SMX)

The combination therapy of TMP-SMX is the therapy of choice for all forms of pneumocystosis (Walzer 2004b). TMP-SMX, which inhibits the folic acid pathway at two distinct steps, is administered orally or intravenously in a dose of 15–20 mg/kg/day trimethoprim (TMP) and 75–100 mg/kg/day sulfamethoxazole (SMX) in three or four divided doses for 21 days in HIV-infected patients and for 14 days in non-infected patients (Walzer 2004b). The parenteral preparation is warranted for gravely ill patients or those with gastrointestinal disturbances. Serum levels of 5–8 μg/mL in adults and 3–5 μg/mL TMP in children and 100–150 μg/mL SMX in both are recommended for maximum efficacy, although there is some question as to the value and practicality of this practice (Walzer 2004b). A significant number of AIDS patients (50–80 percent) experience adverse reactions to this regimen, with gastrointestinal complaints and skin rashes being the most common problems (Stein and Stevens 1995). Other adverse reactions include fever, neutropenia, thrombocytopenia, nausea and vomiting, pancreatitis, nephritis, hyperkalemia, metabolic acidosis, anaphylactoid reaction, and hepatic disturbances (Walzer 2004b). It is thought that the adverse reactions are due to the sulfonamide component, but TMP has been implicated as the cause of skin rashes and hyperkalemia (Velazquez et al. 1993).

Pentamidine

Two parenteral drugs, the cationic diamidine pentamidine isethionate and the dihydrofolate synthase inhibitor trimetrexate, are considered the major alternatives to oral TMP-SMX for moderate to severe pneumocystosis in hospitalized patients (Barry and Johnson 2001).

Pentamidine is administered parenterally as a single daily dose of 4 mg/kg/day or, in some patients, a lower dose of 3 mg/kg/day has been shown to be effective with fewer side effects (Conte et al. 1990). About 50 percent of patients experience adverse effects including local reaction at the site of administration; systemic effects including dizziness, flushing, and cardiac arrhythmias. Hypotension occurs in a significant number of patients and requires vigorous supportive therapy. Nephrotoxicity is a frequent side effect but is usually reversible. The risk of hyperglycemia is related to pentamidine dose, length of administration, and serum levels exceeding 100 ng/mL (Waskin et al. 1988). Other side effects reported were pancreatitis, dysglycemia, hypocalcemia, hypomagnesemia, neutropenia, and hepatic disturbances (Walzer 2004b). Administration of pentamidine via the aerosolized route at 300 mg every month via Respiragard II nebulizer system efficiently delivers high doses of the drug to infected areas, but has been shown to be less effective than other drugs in the treatment of pneumocystosis, probably because it is not well distributed to all lobes of the lungs (Kovacs et al. 2001). It is used primarily as a prophylactic measure.

Trimetrexate

Trimetrexate, a lipid-soluble derivative of methotrexate, was shown to be less effective than TMP-SMX in a controlled trial of hospitalized patients, but better tolerated (Sattler et al. 1994). Trimetrexate is delivered intravenously as a single daily dose of 45 mg/m^2. Bone marrow suppression is the primary side effect associated with this therapy, but administration of folinic acid (20 mg/m^2 every 6 hours) has been found to ameliorate or prevent toxicity. Other side effects reported have been skin rash, peripheral neuropathy, and liver function abnormalities (Walzer 2004b).

Alternatives

Several alternative regimens have been recommended for patients who cannot tolerate or who fail TMP-SMX. These include dapsone at 100 mg daily in combination with TMP taken orally at 320 mg every 8 hours. Atovaquone, a hydroxynaphthoquinone, is another alternative which is administered at 1 500 mg orally per day. Although not as effective as TMP-SMX, it is better tolerated. Dapsone and its combinations appear to be the most efficacious alternative therapies, although some patients still manifest reactions to dapsone which is structurally similar to sulfonamides.

The combination of primaquine and clindamycin has been shown to be most effective against mild to moderate pneumocystosis (Black et al. 1994) but is contraindicated in glucose-6-phosphate dehydrogenase (G6PD) deficiency in which hemolysis has been reported as a major adverse reaction (Korraa and Saadeh 1996). For this purpose, atovaquone has been recommended for patients with G6PD deficiency and who are intolerant to TMP-SMX or pentamidine. The recommended doses are clindamycin at 600 mg (Walzer 2004b) or 300–450 mg (Kovacs et al. 2001) every 6 hours intravenously, with 15–30 mg of primaquine per day orally. Treatment may be initiated with intravenous clindamycin, then switched to oral administration.

Corticosteroids

Adjunctive corticosteroid treatment within the first 72 hours of anti-*Pneumocystis* of moderate to severe

pneumocystosis has resulted in improved survival for many patients (Masur 1992). This important finding led to the recommendation by a panel of experts that steroids be added to the treatment of all patients with moderate to severe pneumocystosis (i.e. arterial oxygen pressure of <70 mmHg, alveolar arterial gradient of >35 mmHg) in the following dose regimen: prednisone 40 mg orally twice daily, days 1–5; 40 mg once daily, days 6–10; and 20 mg once daily, days 11–20 (Anonymous 1990). Steroids are thought to reduce the host inflammatory response, which may then reduce the decline in oxygenation often associated with the first few days of therapy. The principal side effects associated with steroid administration were oral candidiasis, exacerbation of herpes simplex infections, and metabolic effects, such as hypoglycemia.

Mutations in *DHPS* and cytochrome *b*. Is resistance occurring?

TMP-SMX is a combination of two antifolates: trimethoprim (TMP), which inhibits the dihydrofolate reductase enzyme (*DHFR*), and sulfamethoxazole (SMX), which inhibits the activity of dihydropteroate synthase (*DHPS*), in folic acid synthesis. *DHFR* reduces dihydrofolic acid to tetrahydrofolic acid, which can be converted to the kinds of tetrahydrofolate cofactors used in 1-carbon transfer chemistry. *DHPS* catalyzes the condensation of pABA and 6-hydroxymethyl-7,8-dihydropterin pyrophosphate. Since many pathogens, inlcuding *Pneumocystis*, must make their own folates and their mammalian hosts do not, this combination has a high therapeutic index.

Mutations in the dihydropteroate synthase gene (*DHPS*), the target of the sulfa component of TMP-SMX, have been identified in over 50 percent of the *P. jirovecii* samples in surveyed geographic areas (Beard et al. 2000). These point mutations have been associated with sulfa and sulfone resistance in bacterial pathogens (Lopez et al. 1987; Fermer and Swedberg 1997; Kai et al. 1999) and malaria (Brooks et al. 1995). In 1997, the first evidence for such mutations in *P. jirovecii* was identified (Lane et al. 1997). The nucleotide polymorphisms all resulted in changes in the amino acid sequence of the enzyme protein, suggesting evolutionary selection was occurring, perhaps in response to drug pressure. These changes were at amino acids 55 and 57. The pterin substrate binds to threonine at site 55 and arginine at 56. The mutations at position 55 usually substitute alanine for the threonine, which lacks the hydroxyl group needed for binding. The wild-type proline at site 57 is replaced with serine, which may influence the three-dimensional position of Arg56, critical for binding to pABA and sulfa, and the pterin moiety.

Subsequent to these first observations, several studies have been published showing the dramatic spread of the mutant *DHPS* genotypes among *P. jirovecii* infecting human populations around the globe (Helweg-Larsen et al. 1999; Santos et al. 1999; Beard et al. 2000; Huang et al. 2000; Nahimana et al. 2003; Calderon et al. 2004b; Kazanjian et al. 2004; Montes-Cano et al. 2004) and the association of the mutant genotypes with sulfa prophylaxis and potential resistance (Ma et al. 1999; Armstrong et al. 2000; Huang et al. 2000; Kazanjian et al. 2000; Calderon et al. 2004b). In each study, significantly more *DHPS* mutations occurred in sulfa-treated patients than in non-treated study groups. The appearance of the *DHPS* mutations is a relatively recent event, with no evidence for the polymorphisms prior to 1993 (Kazanjian et al. 1998, 2000).

Although the presence of the mutant *DHPS* genotypes and their association with prior sulfa exposure is clear, less clear is how these mutations respond to TMP-SMX therapy. Studies with contrasting results showed a significant decline in survival of patients with the mutations or treatment failure with a sulfa-containing drug (Helweg-Larsen et al. 1999; Nahimana et al. 2003) while other studies have shown no effect in patient outcome (Huang et al. 2000; Kazanjian et al. 2000). Such study outcomes can be confounded by such variables as infections with mixed genotypes, for example. Direct evidence showing a correlation of the *DHPS* gene of *P. carinii* containing the mutations and increased resistance to sulfa was recently demonstrated in a heterologous yeast system, providing evidence that it is likely these mutations will contribute to some decrease in sensitivity to these compounds (Iliades et al. 2004; Meneau et al. 2004).

Last, the encroachment of *P. jirovecii DHPS* mutations into human populations is not relegated to those infected with HIV, rather these mutations are now being reported in association with other types of underlying diseases such as chronic bronchitis (Calderon et al. 2004a). It is apparent that *P. jirovecii DHPS* mutants now enjoy widespread prevalence among the general human population. Whether these mutations will confer a greater survival rate with a higher level of resistance to the sulfa compounds or increased virulence remains to be seen. It should be noted though, that *P. jirovecii* is now being reported in association with a variety of underlying disease states and the issue has been raised as to whether its presence represents a comorbidity factor (De La Horra et al. 2004; Morris et al. 2004).

Atovaquone is a second-line therapeutic for mild to moderate PCP and is used as a prophylactic agent as well. As a ubiquinone mimic, atovaquone binds to cytochrome *b* in the mitochondria, affecting mitochondrial electron transport and parallel processes such as ATP and pyrimidine biosynthesis. Some evidence indicates it may also inhibit ubiquinone synthesis in *Pneumocystis* (Kaneshiro 2001). Mutations in the cytochrome *b* gene of *P. jirovecii* in many patient isolates have been reported (Walker et al. 1998; Kazanjian et al. 2001) and

their association with atovaquone exposure documented (Kazanjian et al. 2001). This finding is not altogether surprising since resistance develops in almost all patients receiving atovaquone as monotherapy for the treatment of malaria (Looareesuwan et al. 1996). Unlike the prevalence of two major mutations in *DHPS*, several polymorphisms have been identified in the cytochrome *b* gene of *P. jirovecii*. Like similar studies conducted with the *DHPS* gene, mutations in the cytochrome *b* gene of *Pneumocystis* expressed in a yeast system was shown to confer a resistant phenotype in vitro (Hill et al. 2003; Kessl et al. 2004).

Despite strong evidence supporting the emergence of new *P. jirovecii* genotypes induced by selective drug pressure, there is no reason as yet to change treatment or prophylactic regimens, and dosing schedules as outlined above remain the recommended procedures(Kovacs et al. 2001).

EPIDEMIOLOGY

As the populations at risk for HIV infection have changed since the 1980s, so too have the demographics of PCP. The medically underserved African American and female populations in the USA are now considered at risk (Justice et al. 2001; Kilbourne et al. 2001; Rabeneck et al. 2001). In these populations, PCP remains a leading opportunistic infection (Centers for Disease Control and Prevention 1999; Fisk et al. 2003). In countries considered to be 'developing' (i.e. Africa, Asia, the Phillipines, and Central and South America), the number of those infected with HIV has increased dramatically, sometimes infecting a third of the population in some sub-Saharan countries. Although PCP rarely occurred in African adults in the first decade of the AIDS pandemic, the incidence has risen dramatically as it has in other developing countries, reaching a 25–80 percent coinfection rate with tuberculosis and a mortality rate ranging from 20 to 80 percent (Fisk et al. 2003).

Moreover, PCP is occurring more frequently in other patient groups that in some cases were rarely affected before, including transplantation recipients, especially in lung transplantation patients (Kubak 2002); patients receiving high dose corticosteroids for brain neoplasms, inflammatory or collagen-vascular disorders, and especially patients with Wegener's granulomatosis (Russian and Levine 2001); in association with asthma (Kuitert and Harrison 1991; Abernathy-Carver et al. 1994; Sy et al. 1995; Dziedziczko and Banach-Wawrzenczyk 1997; Contini et al. 1998); chronic obstructive pulmonary disease (Palange et al. 1994); cystic fibrosis (Royce and Blumberg 2000; Sing et al. 2001); Epstein–Barr virus infection (Stiller et al. 1992); lupus erythematosus (Wainstein et al. 1993; Nguyen et al. 1995; Ward and Donald 1999); rheumatoid arthritis (Oien et al. 1995; Ohosone et al. 1997; Rolland et al. 1998); thyroiditis (Guttler et al. 1993); and ulcerative colitis (Khatchatourian and Seaton 1997; Quan et al. 1997).

The complete life cycle of any *Pneumocystis* species is poorly understood and this has confounded epidemiological studies. The current concepts of the life cycle are discussed in the section on The organism below, but it should be emphasized that neither the route of exit from the lung nor the process it uses to travel to the alveoli is known. There is good evidence that the infection is acquired by an airborne route (Walzer et al. 1977; Hughes 1982), but the agent of transmission has not been identified. In fact, the transmission and acquisition phases are almost completely unknown. Although recent studies have detected *Pneumocystis* DNA in neonatal human and rat populations, an assessment of potential reservoirs in the general population is only in its infancy. Significantly, there is no information about replication within the non-immunocompromised mammalian lung nor its transmission or acquisition among intact hosts.

Seroepidemiologic surveys have shown that the majority of adults in the USA and Europe have anti-*P. carinii* antibodies and healthy children seroconvert at 4 years of age or less (Pifer et al. 1978; Peglow et al. 1990). The primary infection was once thought to be asymptomatic or with generalized symptoms that may be mistaken for a mild viral infection. However, recent studies have shown the high prevalence of *P. jirovecii* in neonates with respiratory symptoms (Vargas et al. 2001), calling into question this widespread assumption. Moreover, reports of the association of *P. jirovecii* in cases of sudden infant death syndrome (SIDS) (Vargas et al. 1999; Morgan et al. 2001; Chabe et al. 2004) also suggest that the organism may be more virulent than once thought. Serological studies have shown that exposure to *P. carinii* is worldwide, although the seroreactivities to specific organism antigens varied among geographic regions (Smulian et al. 1993a).

The evidence on hand supports transmission by immunocompetent individuals or those with subclinical infections. First, more than 75 percent of the human populations surveyed in the USA and Europe are seropositive to *Pneumocystis* antigens by 4 years of age, implying that the organisms are ubiquitous, or at least plentiful, and exposure is a common occurrence. The sheer number of *Pneumocystis*-seropositive immunocompetent individuals argues against the fulminant PCP-infected host as the primary source of infection, as these patients are rare (in relation to the general public) and often hospitalized or have limited access to the general population. More recent data strongly support the concept of host–host transmission. A geographic study of *P. jirovecii* genotypes showed that the genotype with the double mutation in *DHPS* was the most prevalent in the populations surveyed, replacing the wild-type (Beard et al. 2000). The fact that these mutations were not observed before 1993 (Kazanjian et al. 1998, 2000) but had spread over the globe throughout the proceeding

10 years (Miller et al. 2003; Kazanjian et al. 2004; Montes-Cano et al. 2004) argues for a selective pressure and host-dependent spread. Direct evidence is provided by the rat animal model of PCP. Infection with *Pneumocystis* is widespread in the healthy non-immunosuppressed rat populations available from commercial vendors (Icenhour et al. 2001), arguing for highly efficient transmission and maintenance of the infection within these healthy populations. The transmission of the organism from mother to offspring occurs within 1–2 hours after birth in rats (Icenhour et al. 2002) and animals within an infected colony remain positive for *P. carinii* amplicons throughout their residence.

Studies now being conducted in human populations, both immunosuppressed and non-immunsuppressed, point to certain reservoirs of infection in the general population, including patients with underlying disease states besides HIV or overt immunosuppression; neonates; and possibly pregnant women. This is an active and concerted area of research and basic epidemiologic principles for *Pneumocystis* infection should emerge within the next few years.

Asymptomatic colonization

Probable asymptomatic colonization has been shown for both healthy and HIV-infected individuals. Nested or single round PCR amplification targeting the small subunit and large subunit mtLSU of *P. jirovecii* showed 35 of the 47 BAL samples from HIV-infected patients contained *P. jirovecii*- specific DNA; 18 of these came from patients who did not have clinical evidence of *P. jirovecii* pneumonia, suggesting asymptomatic colonization occurred in these patients. In a larger study, 17 of 93 (18 percent) consecutive BALF samples from HIV-negative patients undergoing diagnostic bronchoscopy were found to be positive for the presence of *P. jirovecii* by PCR (Maskell et al. 2003). Analysis of potential risk factors showed only glucocorticoid use [and not lung cancer or chronic obstructive pulmonary disease (COPD)] was associated with the presence of *P. jirovecii*.

The state of pregnancy may facilitate asymptomatic colonization. A study of 33 pregnant healthy women in their third trimester versus 28 healthy women within 15 days of their menstrual cycle showed the presence of *P. jirovecii* DNA in five (15.5 percent) of deep nasal swabs from the pregnant women as compared to none in the non-pregnant women (Vargas et al. 2003). Evidence for the early acquisition of *Pneumocystis* in neonates with the mother as a potential source of organisms is accumulating in both human studies (Miller et al. 2002) and animal studies (Icenhour et al. 2002).

Other factors appear to favor colonization with *P. jirovecii*. In a large study of 367 patients with suspected bacterial pneumonia, the presence of *P. jirovecii* (detected by the same PCR methods discussed above) was statistically associated with old age, concurrent disease, and steroid treatment (Helweg-Larsen et al. 2002).

HOST RESPONSES

Impaired cellular immune function has long been held to be the primary predisposing factor for development of PCP with the CD4 cell playing a central role. The risk of developing PCP in HIV-infected patients increases with a decline in the number of circulating CD4 cells. It is formally recommended that chemoprophylaxis be instituted when the CD4 count in adults falls below 200/mm^3 (Centers for Disease Control and Prevention 2002). However, the decrease in CD4 cells rarely occurs without perturbation of other immune responses and there is now considerable evidence that defects in humoral immunity also contribute to the development of PCP.

Antigens

Immunoblotting studies have identified the major antigens of *Pneumocystis* from humans and animal models that elicit serum IgG antibody responses (Walzer 2004a). There are two distinct antigenic regions that are similar across species lines, the MSGs that migrate between 95 and 120 kDa and a broad-based band at 35–55 kDa that likely contains many discrete antigens.

Each *Pneumocystis* organism encodes about 100 different MSG genes distributed among each of its chromosomes as detected by hybridization of Southern blotted electrophoretic karyotypes (Stringer and Keely 2001). These antigens were localized to the surface of the organism (Kovacs et al. 1989) and have been shown to evoke strong humoral and cell-mediated responses (Smulian and Theus 1994) and to interact with host proteins on lung cells such as fibronectin, vitronectin, and SP-A (Pottratz and Martin 1990a; Limper et al. 1991, 1993; Pottratz et al. 1991; Zimmerman et al. 1992) and the mannose receptor on macrophages (Ezekowitz et al. 1991). It is thought that the MSGs function in a variety of ways:

- by promoting adherence to host lung cells and to other *Pneumocystis* organisms
- by complexing with host molecules to avoid the host immune responses
- by modulating the species of surface MSGs to circumvent the immune response
- perhaps by functioning as adhesions during the mating response (Cushion 2004b).

A sequence common to nearly all MSG mRNAs, the upstream conserved sequence (UCS), has been identified and is present in a single copy per organism genome and resides on a single chromosome (Wada et al. 1995; Sunkin and Stringer 1996). It is thought that the MSG

genes are transcribed only when adjacent to the UCS and the genes are translocated from subtelomeric regions on each chromosome via reciprocal exchange, gene conversion, or a recombination event. The UCS encodes a signal peptide thought to aid in chaperoning the molecule to the endoplasmic reticulum and golgi for processing and ultimately the cell surface where they are the most abundant surface protein.

The MSGs are heavily glycosylated, highly immunogenic, and have been shown to contain protective B- and T-cell epitopes (Gigliotti and Hughes 1988; Roths and Sidman 1992, 1993; Gigliotti et al. 2002). Immunizations with native or recombinant MSG have resulted in conflicting results; some report a protective effect, while others found no such protection (Theus and Walzer 1997; Gigliotti et al. 1998; Theus et al. 1998; Lasbury et al. 1999). Besides the multigene family of MSGs, other multiply repeated genes are present at the telomeric ends of the chromosomes (Schaffzin et al. 1999; Keely et al. 2001; Ambrose et al. 2004). These include the *PRT* family of genes that encode kexin-like subtilisin proteases that are likely involved in processing the signal peptide on the nascent MSG and the MSG-related proteins (MSR) that encode proteins similar but distinct to the MSG. These genes are grouped in arrays at the telomeric ends that vary in number of each gene family member present (Keely et al. 2001). The *PRT* genes exist as a multiple gene family in *Pneumocystis* infecting rats, but only as a single copy in *P. murina* (Lee et al. 2000) and *P. jirovecii* (Kutty and Kovacs 2003), illustrating that there are significant differences among the species of *Pneumocystis*.

The other major antigen group includes proteins that migrate as a broad band between 35 and 45 kDa in *P. jirovecii* (Walzer and Linke 1987) and 45–55 kDa in *P. carinii* and *P. wakefieldiae* (Vasquez et al. 1996). A gene encoding an antigen within the 45–55 kDa region of rat-derived *Pneumocystis* (p55) was cloned and shown to be a single copy gene which hybridized to a chromosome band of about 670 kbp on southern blotted electrophoretic karyotypes (Smulian et al. 1992). The function of this antigen is unclear but has been shown to elicit a cell-mediated response in rats previously exposed to *Pneumocystis* (Smulian et al. 1993b; Theus et al. 1994). An immunodominant epitope was mapped to the 3′ portion of the molecule which contains a 7 amino acid repeat motif. The cells responding to p55 were shown to be CD4+ cells which secreted a Th1 cytokine pattern. The corresponding *p55* gene from *P. murina* was recently cloned and characterized (Ma et al. 2003) and shown to be in single copy as well.

Humoral Immunity

The importance of the humoral arm of the immune response in the control of *Pneumocystis* infection has been shown by several experimental animal studies and indicated by specific immunodeficiencies. *Pneumocystis* infection has been reported in B-cell-deficient mice and other animals (Marcotte et al. 1996; Walzer et al. 1997; Lobetti 2000; Macy et al. 2000) and in patients with hypogammaglobulinemia (Walzer et al. 1989; Esolen et al. 1992). Passive immunotherapy with monoclonal antibodies or hyperimmune sera raised against *Pneumocystis* decreased the organism burden in immunosuppressed animal models (Gigliotti and Hughes 1988; Roths and Sidman 1993). Immunization by intratracheal administration of organisms in CD4-depleted mice was shown to be protective against subsequent *Pneumocystis* challenge possibly by stimulating serum antibodies (Harmsen et al. 1995; Garvy et al. 1997b; Gigliotti et al. 1998; Pascale et al. 1999). Development of spontaneous PCP in colonies of mice with only B-cell defects suggests a role for the humoral branch in the control of the infection (Marcotte et al. 1996). It is clear that macrophages avidly bind and degrade the organism and addition of antisera and complement enhances the rapid internalization and degradation (Smulian and Theus 1994).

Several studies have shown that the organism elicits a strong humoral response. Early studies used the indirect fluorescent antibody assay (IFA), the enzyme-linked immunosorbent assay (ELISA), and complement fixation assay with whole or fractionated *Pneumocystis* organisms or crude antigen preparations to show that most of the human population had antibodies to *Pneumocystis* (Walzer 2004a). Later studies using immunoblotting techniques expanded these studies to evaluate antibodies to specific antigens (Buhl et al. 1993; Lundgren et al. 1993a, b; Smulian et al. 1993a; Chen et al. 1994; Elvin et al. 1994; Smulian and Walzer 1994). Such studies showed that exposure to *P. jirovecii* in humans occurs early in life. By age 3 years, most children have developed antibodies to the organism (Meuwissen et al. 1977; Pifer et al. 1978; Peglow et al. 1990; Vargas et al. 2001; Daly et al. 2002). A study which examined 680 serum samples from healthy adults in several different areas of the world showed 76 percent reacted with the *P. jirovecii* antigens by immunoblotting techniques (Smulian et al. 1993a). Most (60 percent) of the reactivity was observed in the area of 35–45 kDa while only about 30 percent of the sera reacted at ~95 kDa, the area at which the MSG family migrates. Of note, the frequency of antibodies to the MSG region exhibited significant geographic variation, suggesting that different strains of *P. jirovecii* may be predominant in a given area. The high prevalence of serum antibodies and the ubiquitous nature of *Pneumocystis* have confounded efforts to develop serodiagnostic assays. Most serological surveys have shown the frequence and/or level of antibodies to *Pneumocystis* among HIV-infected patients and other immunocompromised hosts were similar to those in healthy controls (Smulian and Walzer 1994). The frequent presence of antibodies in

most human populations has contributed to the belief that humoral immunity contributes little to the host defense against *Pneumocystis* infection.

The MSG family of genes expressed in part or as the whole recombinant protein have been used to probe the immune response in humans. One laboratory expressed a highly conserved region of the carboxy terminus of an MSG gene that was recognized by all serum samples, and thus could not discriminate among patients with active disease, previous episodes, or healthy controls (Mei et al. 1998). More recently, three overlapping fragments that spanned the entire human MSG gene were generated: *MSGA*, *MSGB*, and *MSGC* (Daly et al. 2002). Recognition of *MSGA* and *MSGB* was significantly lower in HIV-positive patients than normal healthy controls. *MSGC* was recognized by patients with previous episodes of PCP. Responses did not vary by geographic location. These data are important because they show for the first time that different regions of the MSG molecule can identify previously unrecognized differences among populations. Serological response may yet play a role in defining disease state.

Cellular immune response

Evidence for the critical role of T cells in resistance to *Pneumocystis* infection has come from observations of the susceptibility of hosts with T-cell deficiencies to pneumocystosis and directly through reconstitution experiments. Infection with HIV, congenital syndromes with T-cell defects, and administration of drugs to suppress the immune system are all factors that place a mammalian host at risk for pneumocystosis. Except for syndromes with specific T-cell defects, the other immunosuppressive states include a more global immune depression. However, adoptive transfer studies, cell depletion, and reconstitution experiments in rodents and the use of knockout mice models have provided good evidence that the primary defect for development of PCP is CD4 cell dysfunction. CD4 cells also interact with B cells and other cells via the CD40–CD40 ligand pathway. Disruption of these interactions resulted in development of PCP in young children with the hyper-IgM syndrome (Levy et al. 1997) and in impaired clearance of *P. murina* from the lungs of mice (Wiley and Harmsen 1995).

Compelling evidence for the critical role of CD4 cells in resolution of pneumocystosis comes from adoptive transfer experiments in which splenic T cells from normal healthy animals or those exposed to *Pneumocystis* were transferred to animals depleted of CD4 cells. The recipient animals went on to clear or substantively reduce their *Pneumocystis* burden (Graves et al. 1994). Chronic administration of anti-CD4 antibodies to BALB/c mice permitted the development of pneumocystosis following inoculation of *Pneumocystis* organisms (Shellito et al. 1990). SCID mice were able to resolve the infection after transfer of splenic cells from genetically matched healthy donors (Harmsen and Stankiewicz 1991; Roths and Sidman 1993). However, when the splenic populations were divided into CD8+ and CD4+ populations, transfer of the former cell population was not effective in decreasing the organism burden (Roths and Sidman 1992). When the SCID mice that were reconstituted with splenic populations were then treated with anti-CD4 antibody, the mice developed *Pneumocystis* infection, while those receiving anti-CD8 antibodies were able to resist infection. *Pneumocystis*-infected SCID mice infused with splenic cells depleted of B cells could not resolve the infections (Harmsen and Stankiewicz 1991), suggesting the CD4 cell was not the only immune effector cell involved in mechanisms of resistance. These studies provide strong evidence for the critical role of CD4 cells in resistance and recovery from PCP but suggest a concerted effort by several immune compartments.

CD8 cells accrue in the lungs of experimental animals with pneumocystosis and can be found in the BALF from human patients infected with *P. jirovecii*. CD8 cells have been shown to contribute to host defenses in experimental mouse models (Beck et al. 1996; Beck and Harmsen 1998). BALB/c mice depleted of CD4 lymphocytes, CD8 lymphocytes, or both CD4 and CD8 lymphocytes, and infected with *P. murina*, showed moderate infection in mice depleted of CD4 lymphocytes while mice depleted of CD8+ lymphocytes cleared the inoculum. This result would seem to show that CD8 lymphocytes are unnecessary for defense when CD4 lymphocytes are available. However, mice depleted of both CD4 and CD8 lymphocytes developed PCP with a significantly higher organism burden than mice depleted of CD4 lymphocytes alone. Thus, CD8 lymphocytes function in the defense against *Pneumocystis* in vivo in the context of depleted populations of CD4 lymphocytes. CD8 taken from the lungs of the CD4-depleted mice proliferated in response to *P. murina* antigen and produced interferon-gamma (IFN-γ) in vitro. Thus the mechanism of host defense by CD8 cells likely involves IFN-γ.

Alveolar macrophages serve as the first line of defense against *Pneumocystis* and clear the organism from the alveoli (Koziel et al. 1994; Limper et al. 1997). The nature of the binding occurs via the mannose macrophage receptor (Ezekowitz et al. 1991) and this binding may be enhanced by host-derived molecules (Pottratz and Martin 1990a, b; Limper et al. 1993) or via the gp120 molecule on the organism's surface (Pottratz et al. 1991). More recent studies showed that additional components were necessary for the macrophage: *Pneumocystis* interaction including β-glucan (Vassallo et al. 1999), which resulted in stimulation of tumor necrosis factor alpha (TNF-α) release; extracellular matrix (Fishman et al. 1991); surfactant proteins (Limper et al.

1995; O'Riordan et al. 1995; McCormack et al. 1997); and Fc receptors (Ezekowitz et al. 1991). Hidalgo et al. (1992) were able to demonstrate induction of the oxidative burst in alveolar macrophages isolated from rats and in a cell line (NR8383) and that the evolution of hydrogen peroxide could be enhanced by complement. The release of nitric oxide by mouse alveolar macrophages was elevated in CD4-depleted *Pneumocystis*-infected mice, but the levels did not correlate with either clearance or severity of infection (Shellito et al. 1996). Urokinase-type plasminogen activator, a protease that facilitates recruitment of inflammatory cells, was shown to participate in the clearance of *Pneumocystis* from the lung (Beck et al. 1999). It is interesting to note that *P. carinii* contains a gene that encodes enolase, a function of which is to activate plasminogen (Fox and Smulian 2001), which may serve to regulate host plasminogen activator. Infection with HIV impairs the mannose receptor-mediated binding and phagocytosis of *Pneumocystis* and also changes the cytokine response (Kandil et al. 1994; Koziel et al. 1998a).

The modulation of cytokine profiles by *Pneumocystis* has primarily been studied in animal models. The proinflammatory cytokines TNF-α, and interleukin (IL)-1 play important roles in host defense against this infection, especially in the early stages (Chen et al. 1992a; Garvy et al. 1997a; Kolls et al. 1997; Limper 1997). The role of IL-1 in the clearance of infection was evaluated in the SCID mouse model (Chen et al. 1992b). Reconstituted SCID mice were able to clear the infection and IL-1 activity in the lung homogenate supernates correlated with an increase during infection and a reduction to baseline after clearance. Antibody to IL-1 could inhibit organism clearance, implicating this cytokine as an important host defense against *Pneumocystis* infection. It is interesting to note that secretion of IL-1 by human macrophages from patients with HIV is significantly reduced, perhaps mediating in part the susceptibility to the infection (Smulian and Theus 1994). Activated CD4 cells produce IFN-γ which has been shown to mediate activation of macrophages. Administration of aerosolized IFN-γ to CD4-depleted mice infected with *Pneumocystis* results in a dramatic reduction in organism burden (Beck et al. 1991), suggesting a role in organism clearance. IFN-γ may mediate this response through induction of nitric oxide synthesis in macrophages (Ishimine et al. 1995) or by other means such as TNF-α release. Investigations into the molecular mechanisms of the roles of some cytokines have produced some puzzling results. In one report, deletion of IFN-γ or TNF-α receptor genes did not adversely affect clearance of *Pneumocystis* infection, while elimination of both receptor genes resulted in severe disease (Rudmann et al. 1998). Some cytokines appear to be produced in response to *Pneumocystis* infection (IL-6), but their role, if any, in host defense remains unclear (Chen et al. 1993), while others seem to modulate the host inflammatory response, such as IL-10 (Ruan et al. 2002; Qureshi et al. 2003) or have no apparent role (IL-4, G-CSF) (Garvy et al. 1997b).

The roles of the costimulatory molecules CD2 and CD28 were investigated after mice with the double knockouts spontaneously developed *P. murina* pneumonia (Beck et al. 2003). Mice inoculated with *P. murina* could develop the pneumonia with the loss of CD28 alone, but the organisms eventually cleared. However, mice deficient in both CD2 and CD28 accumulated CD8+ T cells in their lungs in response to infection and demonstrated markedly reduced specific antibody titers. Cytokine profiles suggested IL-10 and IL-15 may be important for the response to *P. murina*.

Although it may seem apparent that a host response to *Pneumocystis* would be a positive effect, increasing evidence implicates a detrimental role in some cases. Immune reconstitution has been associated with marked cellular inflammatory response, rise in proinflammatory cytokines and chemokines, decreased lung compliance, and impaired oxygenation (Chen et al. 1992c; Wright et al. 1997, 1999b). Adoptive transfer of CD4 cells leads to an early hyperinflammatory response, even in the context of profound immunosuppression by corticosteroids (Roths and Sidman 1992; Theus et al. 1995, 1998). CD4 cells expressing the CD25 phenotype appear to be the cell type mediating this response (Hori et al. 2002). A role for the CD8 cell in the pathological inflammatory response has also been implicated. Immunocompetent mice depleted of CD4 cells exposed to *P. murina* develop the infection with a concomitant influx of CD8 cells and increase in neutrophil numbers, experience altered alveolar-capillary permeability, surfactant dysfunction, and impaired respiration (Wright et al. 1997, 1999a, b, 2001). Depletion of the CD8 cells in these CD4-depleted mice dramatically reduced the associated pathology. In rats, the early hyperinflammatory response after adoptive transfer of sensitized CD4 cells could be ameliorated by addition of CD8 cells (Theus et al. 1995; Theus and Walzer 1997). It appears that both cell types contribute to the pathology of *Pneumocystis* infection, and modulation of this response will require further knowledge of the immune circuitry and host immune status.

ANIMAL MODELS OF INFECTION

Animal models of PCP have played an instrumental role in the scientific investigation of this organism. Without a continuous supply of organisms furnished by an in vitro culture system, researchers have relied on animal models for a source of organisms and for assessment of drug responses. The observations, made in the 1950s and 1960s, that the pneumonia could be provoked in rats and rabbits by corticosteroid administration (Weller 1956; Sheldon 1959; Frenkel et al. 1966) led to the current models used today. This subject is reviewed thoroughly

by Armstrong and Cushion (1994a). The animal models of pneumocystosis have been shown to be strikingly similar to human pneumocystosis in pathology, organism morphology, and most of the basic biology known to date. Drug responses are similar with only few exceptions (Walzer 1994).

There are basically two types of animal models of pneumocystosis. The first type is a provocation of organisms resident within the lung or acquired from ambient air by chronic administration (e.g. 6–8 weeks) of corticosteroids or another immunosuppressant. The immunosuppressants can be administered in the drinking water (e.g. dexamethasone 1 mg/L) or by injection (e.g. Depo-Medrol, 4 mg/kg/IM or SC). This immunosuppressive regimen is associated with wasting, increased debility, and marked involution of all lymphoid tissues (Walzer et al. 1984a, b). Lymphopenia in the rat model was found to result in inverted CD4/CD8 cells, similar to that in AIDS patients. Oftentimes, an antibiotic (e.g. tetracycline) is concurrently administered to prevent secondary bacterial infections resulting from the immunosuppressed state of the animals. Administration of a low-protein diet (8 percent) has been reported to exacerbate the infection in the rat model (Hughes et al. 1974b). It is presumed that organisms within the lung begin to replicate or replicate without clearance once the immune system is sufficiently suppressed. This has been shown by experiments in which rats are received into barrier facilities that exclude all contact with ambient air, are immunosuppressed, and develop the infection (Cushion et al. 1993). The only source of organisms are those within the lungs of the animals. Rats receive the infectious propagules through an airborne mode, as shown by development of the infection in immunosuppressed *Pneumocystis*-naive animals placed in the same room (but not in contact) with *Pneumocystis*-infected rats (Walzer et al. 1977; Hughes 1982).

The second approach to establishing *Pneumocystis* in animal models is via inoculation. A surgical procedure in which the organisms are instilled into the trachea of lightly anesthetized, immunosuppressed rats (Bartlett et al. 1987), or mice (Bartlett et al. 1991), or instillation via a feeding cannula (Boylan and Current 1992) is used for inoculation. An immunosuppressant regimen as described above is required for replication of the inoculated organisms.

Both methods are useful for studying different aspects of the infection. The 'naturally' acquired infection permits an evaluation of the pathological processes that more closely mimic the actual disease progression. The inoculated model affords standardization in drug evaluations, a consistent supply of organisms, and the ability to use a genetically defined population.

Several species of animals have been used for the study of pneumocystosis by employing either one or both of these techniques. Rats and mice are the models used by most researchers. The ferret model had been used because of its larger size, permitting BAL, but now is rarely employed for studies (Armstrong and Cushion 1994a).

Other approaches to reducing the immune response are gaining favor, especially those designed to preferentially deplete the CD4 cell populations. CD4 cell depletion has been accomplished by administration of anti-CD4 monoclonal antibodies administered on a weekly basis or by implantation of a hybridoma which secretes monoclonal antibodies to this population (Shellito et al. 1990; McFadden et al. 1994; Thullen et al. 2003).

Animals rendered immunodeficient by genetic defects have been used on a more limited basis, but afford a model with fewer manipulations than the previously described ones. Many colonies of immunodeficient mice or rats are often infected with *Pneumocystis*. Homozygous scid/scid mice are especially prone to the infection as well as nude mice and rats (Roths et al. 1990; Sidman and Roths 1994). Neonate rabbits can be naturally infected with *Pneumocystis* without administration of immunosuppressants during their first few weeks of life (Soulez et al. 1988). This model has primarily been used for ultrastructural studies.

CONCLUSIONS

The placement of *Pneumocystis* in the Kingdom Fungi is now generally accepted. The genus has been placed within the Ascomycetes within its own family and order. Four species have been described: *P. jirovecii* which infects humans (Frenkel 1999); *P. carinii* and *P. wakefieldiae* from rats (Frenkel 1999; Cushion et al. 2004a); and from mice, *P. murina* (Keely et al. 2004).

Experimental models and human epidemiologic studies have implicated neonates as potential reservoirs of infection, as well as members of the general population that may be only slightly immunocompromised. Association of *P. jirovecii* with respiratory symptoms and with SIDS calls into question the concept of primary infection as a benign event. The association of *P. jirovecii* with underlying disease states such as COPD suggests its presence may be a comorbidity factor.

P. jirovecii has evolved mutations in the *DHPS* gene which have been linked to sulfa prophylaxis. The *DHPS* mutations in *P. jirovecii* have been reported in many different countries and continents, evidencing the rapid spread of these strains. Mutations in the cytochrome *b* gene, the target of atovaquone, have been reported, raising the specter of drug-resistant organisms.

The *Pneumocystis* Genome Project and efforts of individual investigators have contributed to a better understanding of the metabolic capacity of these organisms and the molecular processes of replication. Genes associated with mating, meiosis, cell cycle, sterol metabolism, heme biosynthesis, and energy production have

been identified. Identification of unique cycles or genes should provide new strategies and desperately needed drug targets.
